Introduction

TEXTBOOKS on psychology usually preface the text with an apology for the difficulty of defining psychology. A HANDBOOK OF ABNORMAL PSYCHOLOGY ought to begin with a triple apology, because in addition to the obvious difficulties of defining the major subject it is not at all easy to define the concept of "abnormality," and even the connotations of the word "handbook" are far from obvious. We shall not attempt to give any new meaning to the term "psychology," but shall take it to denote the scientific study of the behaviour of organisms. Nor shall we worry overmuch about the general designation of this book; handbook is as handbook does. But we shall devote a little time to a discussion of the meaning of "abnormal," if only because our use of the term will be found to differ somewhat from that often accepted in psychiatry and clinical psychology.

As has frequently been pointed out, the word "abnormal" is used in at least two quite distinct senses. It may be equated with the *statistically unusual*, or it may be equated with *deviations from the ideal norm*. Often the two are combined, so that deviations from the norm which are decidedly unusual are called "abnormal" only when they are in an undesirable direction. Thus an I. Q. of 50 is considered abnormal, but not one of 150; cowardice, but not bravery; neurosis, but not superior adjustment.)

As used in psychology, the term has come to refer to certain *unusual* and *maladaptive* states, such as schizophrenia, hysteria, anxiety state, and the like; this usage appears to have been taken over from psychiatry, where these behaviour patterns are regarded as medical diseases; As will be shown later (Chapter 1), this usage is not really justified by the facts; mental abnormalities do not represent qualitative disease entities having specific "causes." They resemble rather such continuously varying features as height, intelligence, hair colour, and the like, and demand quite a different type of analysis from that appropriate to "diseases."

It is for this reason that we have rejected the traditional arrangement of books on abnormal psychology, which closely follows the psychiatric mould. Hunt (1951) has put the situation very well: "Clinical psychology in (the) methodological sense is a more mature science than psychiatry. It is definitely experimental, if at times somewhat shakily so. As an experi-

mental science, it has much to offer psychiatry, as I think many psychiatrists realize. For once, however, I am not advocating the 'team' concept, although it is one of my firmest beliefs. I would rather suggest that psychiatry attempt to stand upon its scientific feet, if only because of the good example it would set us in clinical psychology; far too many of us clinicians, instead of bringing our experimental tradition to the assistance of psychiatry, flee to the empirical ambiguities of psychiatry in an attempt to escape the rigorous scientific demands of our own discipline." This is precisely what we have attempted to do here—bring the experimental tradition of psychology to bear upon the "abnormal" behaviour of the organism. For reasons which will become apparent, we have rejected the psychiatric framework outright, preferring not to be bound and constrained by diagnostic schemes of dubious validity and known unreliability. Where the experimental findings summarized by us were couched in terms of such a system, we have of course had to make such use of them as we could, but we have, whenever possible, translated these classificatory schemes into a more empirical framework along the lines of dimensional analysis, outlined in Chapter 1.

In thus attempting to break away from the traditional frame, we have encountered two main difficulties. In the first place, much discussion had to be devoted to methodological problems. As long as clinical and experimental psychologists are content to take psychiatric diagnosis as their criterion, so long will their experimental designs be of exemplary simplicity and elegance—and their results equivocal and unrepeatable! But once we begin to question the validity of psychiatric diagnosis, and demonstrate its obvious lack of reliability, we are cast adrift on rather more turbulent waters, and have to consider seriously the problem of experimental design and methodological adequacy.

In the second place, most of the published evidence was found to be useless for our purpose, and had to be discarded. Less than one-fifth of the papers and books examined have been included, and even so the reader will find that what remains often gives rise to critical discussion rather than to enlightenment. We have preferred the positive to the negative approach, leaving out whole areas which traditionally would have been included (the vast literature of the Rorschach

technique is one example) because detailed investigation revealed all dross and no gold (Eysenck, 1958), and including instead much less well cultivated areas (such as dark adaptation, or conditioning) because these seemed to hold out a more definite promise of future usefulness. We have little doubt that our critical judgements, leading to *exclusion*, can be justified by factual reference; we have less confidence that the same would at present be possible with respect to those judgements leading to the *inclusion* of material about which there is as yet not very much evidence. The book as a whole presents a point of view; it is in recognition of the fact that this point of view may easily be mistaken that we have prefaced the book with a quotation from Terence which William Harvey included for a similar purpose in his *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (1628).

Our conception of abnormality, then, is not in terms of classes of people suffering from mental diseases produced by definite "causes"; it is rather in terms of the defective functioning of certain psychological systems. The delineation of these systems, and the mapping out of the laws according to which they work, is the task of experimental psychology. There is no pretence that all is known about these systems, or about the laws governing their working. We are only too well aware of the low level of knowledge, and the high degree of speculation, which are so characteristic of even the most developed parts of psychology. But poor as this may be as a base, it is all there is; good intentions cannot conjure up scientific knowledge, and it is better to rely on a small but secure base, than float on insubstantial clouds of putative and supposititious generalizations without reference in reality.

Whenever possible, we have supplanted the usual paradigm of psychiatric research— x members of class y showed behaviour z —by what to our way of thinking is a superior paradigm: change in the independent variable x effects a change y in function z . In this paradigm, change y might be in the direction of making function z more "abnormal," or it might be in the opposite direction; provided the experiment included abnormality of functioning as a referent, it was considered to be relevant to our endeavour. Thus an experiment in which a hundred schizophrenics had been given the Rorschach test, and their performance discussed and perhaps compared with that of other groups, would not be included; an experiment in which experimentally induced anoxia caused a decline in dark-vision performance would be included. Indeed, while nearly all of the material traditionally included in books on abnormal psychology would have been gathered from experiments on abnormal groups, such as neurotics and psychotics, much of our material comes from normal groups. Readers who do not feel

in sympathy with this approach may like to consider that there are many textbooks written along the lines we have criticized; with one or two partial exceptions there is none which treats the subject in the manner here advocated.

A word may need to be added about the phrase "change in the independent variable x ." These words have their usual meaning when we deal with the effects of administering a drug, carrying out an operation on the brain, or giving a series of cerebral electroshocks. It carries a slightly different meaning when this change in variable x is effected by choosing different groups of subjects (human or animal) whose positions on a continuum presumed to be highly correlated with x differ significantly. Thus Spence and his colleagues have carried out a series of investigations into the effects of anxiety (x) on conditioning and learning by comparing the performance of different groups of students scoring respectively high and low on a questionnaire presumed to be a measure of anxiety. While we cannot afford to reject any method of testing our hypotheses, attention should be drawn to the dangers inherent in this procedure. The continuum in question may not in fact be isomorphic with the hypothetical variable x ; the method used for allocating people to positions on the continuum may have low reliability and low validity; position on the continuum may be indicative of a chronic state which produces different effects from those consequent upon acute and sudden stimulation-produced increases in x . Fortunately, all these points are open to empirical study, and much interesting material should emerge from a detailed investigation of the advantages and disadvantages of this paradigm.

Another point arises in connexion with the use of factors or continua in this type of research. As will be seen in Chapter 1, it is often possible to show that certain psychiatric groups have clearly assignable positions in the dimensional framework produced by the combination of factors or continua (as an example see Fig. 1.7 in Chapter 1). The question is sometimes put whether the dimensional framework is not merely a restatement of the original psychiatric type of classification. The answer, of course, is simply that the degree of correspondence observed is of some interest in making possible the translation of experimental findings from one field to the other. It is not, however, used or intended in any sense as proof of the correctness of the dimensional system, which is derived independently from the empirical relationships between experimental and behavioural measures of an objective kind applied to groups of normal and abnormal subjects. Even if there were no correspondence at all with psychiatric diagnostic classifications, this would not in any way invalidate the empirical findings.

Accumulation of facts, while indispensable, is not

enough in science; "those who refuse to go beyond fact rarely get as far as fact." Hence we have been particularly concerned to do two things. We have tried to use the laws and hypotheses of general, experimental psychology to account for the facts presented; it will be noted, for instance, how the Yerkes-Dodson Law appears to integrate the superficially heterogeneous content of many different chapters. (A quick look through a score of textbooks of abnormal and clinical psychology shows that none of them even deigned to mention this law!) We have also tried, where this deductive process could not be used because of the absence of well-substantiated laws in a particular field, to form generalizations from the available data, and thus suggest certain general rules or hypotheses which are sufficiently precise to admit of experimental tests. Thus there is throughout this book a stress on *integration through theory*, an attempt to see abnormal psychology as a part of general, experimental psychology. The laws of learning theory, to take but one example, apply no less to neurotics than to rats and college students; should it not be the task of the psychologist to deduce the details of abnormal behaviour from such general laws? This attitude has governed our view on the problem of treatment also, and on the relationship between abnormal psychology, or psychopathology, and psychiatry. Jaspers has put the case very clearly in his classical *Psychopathologie*—

Psychiatry always deals with individual people in their totality . . . But while the work of the psychiatrist is entirely with individual cases, he nevertheless requires to be also a psychopathologist, to look for general concepts and rules, in order to solve the problems presented by the single case. (If the psychiatrist in the course of his practical work) . . . makes use of science as only one of his aids, to the psychopathologist this science is an end in itself. He wishes to know and understand, characterize and analyze, not the individual person, but the general case. He is not concerned with the therapeutic use of his science . . . but only with truth, with facts, with connexions, and with proof.) Not for him are empathy and understanding as such; they only furnish him with material. (He requires ideas which can be conceptualized, which can be communicated, which can be fitted into an orderly scheme and which can be systematized . . . Science requires conceptual thinking which is systematic and can be communicated: Only in so far as such thinking has been developed can psychopathology claim to be scientific. That part of psychiatry which is art and expertise, which cannot be communicated but at best handed over in personal contact to susceptible disciples, cannot be the subject of printed explanation. Psychiatric instruction is more than the communication of conceptualized knowledge and more than the teaching of scientific facts.) A book which is concerned with psychopathology can only offer scientific knowledge, and is valuable only in so far as it does precisely that. With a full realization of the importance of experience for

practical treatment, and for the analysis of individual cases, we will nevertheless restrict ourselves consciously to those matters which are properly the subject matter of scientific knowledge.

While we have thus concentrated on *facts*, and *laws* relating facts together into an organized whole, we have not tried to erect any kind of grand metaphysical system, all-embracing and all useless. As Robert Boyle said: "It has long seemed to me to be none of the least impediments of the real advancement of true natural philosophy that men have been so forward to write systems of it." And as Bacon said of such system builders, they had "with infinite agitation of wit, spun out of a small quantity of matter those laborious webs of learning which are extant in their books . . . To what purpose are these brain-creations and idle plays of power? . . . Everyone philosophizes out of the cells of his own imagination, as out of Plato's cave." In its present humble state, psychology can at best support on a factual basis certain low-order generalizations; to go beyond these is to court disaster. Such generalizations are the building stones for all future advance; hence the importance of deriving them from the facts in a proper quantified manner. "Just as the ears are made for sound and the eyes for colour, so the mind of man is meant to consider quantity, and it wanders in darkness when it leaves the realm of quantitative thought." Thus Kepler, and we may perhaps add Roger Bacon's dictum of seven hundred years ago: "Physicians must know their science is impotent if they do not apply to it the power of mathematics."

A point of overriding importance has always seemed to us to be the *choice of variables* to be measured in our attempts to describe abnormal behaviour. This choice has in the past been made too often in a haphazard manner, determined by fashion (Rorschach), ease of obtaining data (questionnaire), or whim. Measurement in science grows out of a theoretical system, and is an inseparable part of that system; alter the system, and you alter the meaning and process of measurement. Only measurements so anchored have scientific meaning, and are capable of interpretation which is not arbitrary, subjective, and indeterminate. I have tried to make this point in detail elsewhere (Eysenck, to be published), and will not reiterate the arguments in its favour. It is necessary, though, to insist on it because several chapters are devoted to detailed discussions of the correct choice of variables in the investigation of mental abnormality. Thus the chapter by Granger attacks in detail the choice of variables in the study of perception, and the chapter by Furneaux sets out a system of description of problem-solving behaviour which specifies the most relevant variables in that field. In the fields of learning and conditioning, a similar attempt has been made by

the writer (Eysenck, 1957) elsewhere, and consequently less space had to be devoted to this aspect by the authors of these chapters.

Our general outlook has of course governed the way in which the book has been organized. Part I deals with the description and measurement of abnormal behaviour in terms of sensorimotor functions, perceptual functions, thought processes, ego functions, and so forth. Part II deals with the causes and determinants of abnormal behaviour, such as genetic factors, constitutional factors, conditioning and learning, childhood and other environmental factors, and the like. Part III deals with the experimental study and modification of abnormal behaviour, concerning itself with the effects of drugs, psychotherapy, electroshock, surgical treatment, and so on. Like most classifications, this one merely serves the practical purpose of organizing the experimental material; it does not aspire to have more than heuristic value.

Many readers will undoubtedly feel that certain topics ought to have been included which in fact have been omitted. Ought a book such as this not have a special chapter on old age, which is probably responsible for more types of abnormal behaviour than many factors included? Should hypnosis not have been given extensive treatment? The list is endless, and we have no defence. These and many other topics ought to have been included but were not. Perhaps if a second edition is called for the publishers will be less insistent on our not overstepping the total number of words allocated to this venture . . . The remedy is in the reader's hand.

We have tried, in selecting our material, to avoid overlapping with handbooks devoted to other fields of psychology. Stevens's *Handbook of Experimental Psychology*, Lindzey's *Handbook of Social Psychology*, Carmichael's *Manual of Child Psychology*, and Stone's *Comparative Psychology* mark out fields of study which are relatively separate from our own, and it will be seen that only a very small percentage of the references in this HANDBOOK will be found in these other volumes. This may serve as evidence that the field of "Abnormal Psychology" has indeed a separate and independent existence, even though its definition, as mentioned before, may be difficult and heuristic; indeed the contents of this HANDBOOK may have to serve as a kind of operational definition of the field covered.

A final word may be in order to explain the composition of the team of writers whom I asked to contribute the various chapters. Originally I conceived the notion of writing a book such as this fifteen years ago when the exigencies of the war threw me into contact with psychoneurotic patients at the Mill Hill Emergency Hospital. Having little knowledge of the field, I naturally turned to the available textbooks on psychiatry and abnormal/clinical psychology. The perusal

of some fifty of these left me in a state of profound depression, as none of them contained any evidence of properly planned or executed experimental investigations, or even the realization of the necessity for such. Nor did I find that concise and consistent framing of theories and hypotheses which usually precedes experimental investigations; all was speculation and surmise, laced with references to "clinical experience." Michael Faraday's words seemed only too apposite: "They reason theoretically, without demonstrating experimentally, and errors are the result." It was not until I turned back to Kraepelin that I found an attitude of mind which was willing to carry on the traditional brick-by-brick accumulation of evidence on the basis of properly planned experimental inquiries, and I soon noticed that much interesting and important work had in fact been done and reported in the Journals, although it had not penetrated into the textbooks. What more obvious, then, than to plan to gather together all these widely separated facts and theories into a textbook of abnormal psychology on a factual basis?

Accumulating material at the rate of a thousand articles and fifty books a year, I finally came to the conclusion that I could only write this book if I gave up all hope of doing research for at least three years. Once I had faced this choice in a determined fashion, the obvious solution suggested itself. During those years, there had gathered in my department a group of people who had specialized in different aspects of the general field of psychopathology, who had mastered the literature in their special areas of competence, and who had carried out experimental investigations in these various disciplines. Instead of trying in vain to duplicate their expertise, why not make use of their ability and unique experience to make the project a reality? Their enthusiastic collaboration was readily secured, and the general shape of the book was hammered out in a series of meetings. One or two colleagues from the psychiatric staff of the Maudsley and Bethlem Royal Hospitals had to be called in to cover areas which they were more competent to review than anyone in the Department, but with this exception all the chapters were contributed in the event by members of the Psychology Department. Some of these have since left and gone to the ends of the earth—Australia, U.S.A., New Zealand; one died under tragic circumstances, and was much mourned by all of us. But the book finally reached completion, and it remains for me to thank all my colleagues for their co-operation and their help. Each is responsible for his or her own chapter; I have not considered it my duty to censor opinions, but merely to avoid too much duplication, and to advise when asked to do so. Nor have I tried to ensure uniformity of outlook or agreement on all controversial points; what unity there is is due to the

integration achieved by living, working, and arguing together. On one point, however, there is no disagreement whatever; the absolute necessity, namely, of applying the highest standards of experimental design and statistical treatment to the complex and perplexing problems offered by this fascinating but difficult field. It is for this reason that the dedication is to E. Krapelin, the first person to be trained in the psychological laboratory, and to apply experimental methods to abnormal psychology. It is sobering to consider, if only his outlook had prevailed in psychiatry, how much farther advanced our knowledge would now be! And how much less occasion there would be for what Huxley has called "the great tragedy of Science—the slaying of a beautiful hypothesis by an ugly fact."

CHAPTER 1

Classification and the Problem of Diagnosis

H. J. EYSENCK

THE importance of classification in the field of abnormal psychology is well indicated by Cattell's dictum (1940) that *nosology necessarily precedes aetiology*. Marzolf (1945) expresses the same thought when he says that the *establishment of syndromes is preliminary to the discovery of aetiologies*. Before we can reasonably be asked to look for the cause of a particular dysfunction or disorder, we must have isolated, however crudely, the dysfunction or disorder in question, and we must be able to recognize it and differentiate it from other syndromes. The very term "abnormal" implies a principle of classification; we could not look for causes of "abnormality" unless we had some conception of what we mean by "normal," and what kinds of deviations we would agree to consider "abnormal." Having once given a rough and ready answer to this problem, we would then find that our group of "abnormal" persons was still too heterogeneous to make the concept of a single general cause a reasonable one, and we would have to pursue our efforts at classification by recognizing such subgroups in our population as mental defectives, psychotics, neurotics, and so forth.

Traditionally, classification in the field of abnormal psychology has been by means of specific diseases or syndromes; we speak of hysteria, or schizophrenia, or manic-depressive psychosis in much the same way as we speak of tuberculosis, or neurosyphilis, or cancer. This is probably due to the medical tradition in this field; psychiatry has always paid more attention to the thought habits of general medicine than to the facts and methods of modern psychology. It is probably advisable to begin this chapter by investigating the rationale underlying current diagnostic systems, and to investigate also the question of whether better methods may not now be available for the solution of this fundamental problem.

Fig. 1.1 shows a diagrammatic view of a typical medical disease, namely tuberculosis. We have a "cause," namely the tubercle bacillus, acting on an

organism predisposed by constitutional and environmental factors to react to the bacillus. The illness, when it develops, is characterized by various symptoms, some of which have been indicated in the figure. Methods of cure are available, and reasonable estimates of final outcome can often be made. In other

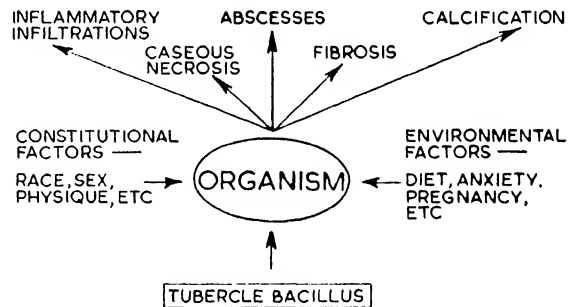

FIG. 1.1. DISEASE SYNDROME IN MEDICINE: TUBERCULOSIS

words, we have a rational system of aetiology, symptom-complex or syndrome, diagnosis, prognosis, and treatment. Diagnosis may be made on the basis of either the noxious agent which is designated the "cause" of the disease, or on the basis of the syndrome which is typical of the disease; which is done in practice depends on many factors which cannot be discussed here. Both methods may be used simultaneously.

This simple picture does not always correspond to reality. Neurosyphilis, for instance, is a term which includes all those disorders of the nervous structures, the envelopes surrounding them, and the blood vessels traversing them, which are caused by *treponema pallidum*. Its symptoms may be of almost any variety. "The symptoms of parietic neurosyphilis are protean in character and form almost any syndrome." (Cecil and Loeb, 1955). In other words, sometimes there is no close correspondence between "cause" and syndrome,

and it becomes difficult if not impossible to diagnose the former from the latter. This, however, is unusual, and most frequently there is some degree of correspondence between the two.

Historically, the discovery of the syndrome usually precedes the discovery of the "cause" of the disease (Mettler, 1947; Castigliani, 1941; Singer, 1928; Wittington, 1894). Thus the Roman writer Celsus (25 B.C.-A.D. 50) in his book *De Medicina* already discusses tuberculosis (Spencer, 1935), although the discovery of the tubercle bacillus did not take place until 1882. Nor did treatment always wait upon the discovery of the "cause"; Aretaeus the Cappadocian, who lived in the third century A.D., is credited with the advocacy of a milk diet in phthisis. "In the eighteenth century, the cause of scurvy was not known, but fresh fruit juices were used to prevent its occurrence. Jenner did not know the cause of smallpox, nor why vaccination should afford protection against the disease. John Snow died long before Koch saw the cholera vibrio under his microscope, but he knew that removing the handle of the Broad Street pump was an effective public health measure."

(How does all this apply to psychiatry? As is well known, knowledge of the "causes" of psychiatric disorders is almost completely lacking and consequently diagnosis is based largely on symptoms and syndromes.) No satisfactory system of classification on this basis has been worked out, and it is difficult to disagree with Cameron (1944) when he points out that—

All current attempts at classification of functional personality disorders are unsatisfactory; this is true for the neuroses as well as for the psychoses. No causal organisms have been implicated, hence we cannot fall back upon them as we can in the specific infectious diseases. There are no characteristic organic lesions, as there are in the systemic diseases; and the central nervous system exhibits no consistent changes that can be correlated with the syndromes as in neurological disorders. Physiological and biochemical studies do not support the older assumptions that fundamentally different metabolic processes underlie different forms of personality disorder. . . . It is important for persons working in the abnormal field to realize that the current official psychiatric classifications are not based upon final and convincing scientific evidence. They are children of practical necessities. Decisions as to the group in which a given behavior disorder shall fall depend upon schemata that actually were adopted, both in this country and in Great Britain, by a majority vote of the practising members of large associations. In some very fundamental respects these systems of classification represent frank compromises between dissident factions, as one can readily observe by reading the successive committee reports.

This interesting extension of the democratic process of majority rule into the scientific and medical fields

appears to be the final outcome of the method of classification devised by Kraepelin. As Degan (1952) points out—

His method of classification in its procedural aspects remains as the most popular, if not the only method of analyzing the complexities of psychiatric disease and synthesizing these into some type of order. His method may be described as the integrative resolution of the clinical observation of many cases with respect to their etiology, onset, symptomatology, course, and prognosis. Classificatory schemata derived in this manner are usually presented in the form of an essentially heuristic argument, and their ultimate validity is assessed in terms of the amount of agreement between the proposed system and the clinical experience and conceptions of the professional audience. Certainly, integrative clinical observation is well established as an exceedingly valuable method in medical research. However, the potential difficulties inherent in the communication of the subjective analytic and synthetic processes and criteria, and the absence of subsequent objective validation are obvious. . . . Official classifications follow fundamentally the same procedures as that of Kraepelin with only the additional formalization of the process of acceptance or quasi-validation. To say the least, this is a novel method of testing a scientific theory.

(The failure of psychiatry to produce an acceptable classificatory system is obvious, not only in the necessity of introducing non-scientific criteria such as popular agreement, but also in the consistent lack of reliability shown in the actual use of the system by experienced psychiatrists. The evidence has been reviewed elsewhere (Eysenck, 1952), and it is clear that correlations between diagnoses made independently by different psychiatrists are too low to be readily acceptable as descriptive of the patients who are being examined. In part this is no doubt due to the low reliability of the ratings made of the symptoms which enter into the various syndromes. (Cattell (1957) reports a correlation of only 0.25 between experienced psychiatrists rating the symptom "anxiety" in eighty psychiatric patients!) but in part it undoubtedly reflects the faults of the general system which is being employed. No improvement is likely to occur until the basis of the present method is changed, and more modern methods substituted for those currently in use.

The first essential is probably the banishment of the notion of *disease* from the field of the functional mental abnormalities.) Already in 1913, Jaspers pointed out that there are three *types* of psychiatric disorders. In the first group are those psychological abnormalities which are based on physiological and neurological disorders of the brain and the central nervous system—

The psychiatrist appears to be rescued from the difficulties presented by the concept of "disease" in those cases where he finds a *somatic* process to be responsible

for the (psychological) disorder, a process which is objectively demonstrable and measurable. [In this connexion] psychopathology is only a means to an end, namely the discovery of physical symptoms. Physiology, not psychology, is the final aim of medical research. As physicians, we are concerned with the body alone. . . . Only those psychological processes are diseased which are produced by diseases of the brain.

(Jaspers' second group contains the psychoses—

Which do not manifest somatic disorders of a kind which would enable us to diagnose psychosis by reference to them. Consequently the notion of disease, is here primarily and exclusively related to psychological events. It is true that in many cases there occur somatic phenomena which suggest that perhaps some fundamental somatic cause may be at work and discoverable in the future. But in many cases these phenomena are absent. Hence it appears probable that certain definite somatic diseases will have to be excluded from this group and apportioned to the first group. Nevertheless, a clearly differentiated and independent group of disorders will remain, purified by this process of exclusion. Research into these disorders would be directed towards the discovery of psychological factors (*Grundfunktionen*) whose disturbance would render intelligible the manifold symptoms, rather in the same manner as in the first group.

In the third group of disorders we find the undesirable variants of humanity (*die unerwünschten Variationen des Menschseins*), and here there can be no question of somatic foundations for organic diseases. The body only enters the picture as it does in relation to healthy psychological development. Nor is the disease process . . . something quite novel compared with the preceding stage of health. We are dealing with fundamental properties of human existence (*Grundeigenschaften menschlichen Daseins*) . . . Disorders in this group would be the neuroses, the character disorders, and criminal and other asocial propensities.

It may be possible to simplify this division even further. Eysenck (1957) has pointed out that the term "psychiatry" does not denote any meaningful grouping of problems or subjects of study, and that much of it is only of incidental relevance to psychology—

Few psychologists would probably disagree with the first of these two statements; anyone looking through the list of disorders officially falling under psychiatry will find it very difficult to find anything in common between G.P.I., schizophrenia, psychopathic behaviour, Alzheimer's disease, conversion hysteria, epilepsy, and Parkinsonism. From the point of view of the psychologist we may perhaps divide psychiatry into the *medical* part, dealing with the effects of tumors, lesions, infections, and other physical conditions, and the *behavioural* part, dealing with disorders of behaviour acquired through the ordinary processes of learning. Most neurotic disorders will come under this second heading, as well as possibly some or most of the schizophrenic and manic-depressive (functional) psychoses. Several related principles spring to mind, such as gross—as opposed to minute—changes

in the nervous system, or irreversible—as opposed to reversible—changes. The position, of course, is complex, and in the present state of ignorance no very clear-cut differentiations are possible; nevertheless, the distinction intended will be reasonably clear from what has been said, even though it cannot be claimed to be absolute, and even though borderline cases may have to be recognized.

Regarding the medical type of case, I believe that the contribution of psychology is secondary. Psychologists may occasionally be helpful in diagnosis, and even in relation to prognosis. . . . Similarly, psychological tests, particularly those of sensory dysfunction, may often give a timely warning of incipient neurological dysfunction and even help in its localization. . . . But these contributions, important though they may be, are secondary to the work of the neurologist, physiologist, and the surgeon. Psychology in this field is correctly conceived of as an ancillary. The position is quite different when we turn to the vast group of behavioural dysfunctions where there is no known neurological lesion or dysfunction.

Here, so the argument continues, psychology is the fundamental science, and rational methods of treatment have to be based on a thorough knowledge of modern psychological theory, particularly learning theory. This view is also explicitly put forward by Jaspers when he writes: "The study of psychology is indispensable for the psychopathologist as is the study of physiology for the somatic pathologist."

If psychology is of necessity secondary to other sciences in the investigation of the medical types of psychiatric disorder, it would also seem to follow that these disorders do not present any particular methodological difficulties in research and treatment, however complex in practical detail such investigations may be. In fact, one might reasonably ask why many of these disorders are usually dealt with by psychiatrists at all, seeing that in principle they are no different from other medical disease. It is true that psychological symptoms and changes play a prominent part in many of them, but these are secondary and are not really susceptible to psychological treatment. There are similar psychological changes in connexion with many diseases (depression associated with tuberculosis, for instance), yet these are not classed with the psychiatric disorders. It might be urged that the cortex and the C.N.S. underlie human behaviour in a very special sense, and that consequently it is reasonable to group diseases affecting these structures with those behaviour problems we call neuroses and psychoses. Hormonal secretions, however, or the autonomic system, equally determine behavioural reactions, yet disorders of these systems are not usually considered part of psychiatry. The answer is probably an historical one. The mental symptoms attending cortical disorders are much more obvious and more easily observed than are the physical ones, and consequently there was a very natural

confusion between these states and the psychotic and neurotic ones. G.P.I. is a very obvious example of this. Only fifty years ago many psychiatrists still believed that this was due to psychological causes, and treated it by means of psychotherapy. As Bruetsch (1950) points out—

The greater frequency of general paresis in males was explained by the preponderance of intellectual work in men, and by their more frequent contact with the strains of the world, with ambitions and frustrated hope. The small number of general paretics in the peasant class was explained on the grounds that they were relatively free from emotions and passions. . . . Krafft-Ebing, the famous Viennese professor of psychiatry, gave the following etiological possibilities for general paresis: dissipation in alcohol and love, heredity, smoking ten to twenty Virginia cigars, excessive heat and cold, trauma to the head, exhaustive efforts of making a living, weak nerves, and fright. Among women, the menopause was given as the most important factor because the onset was frequent between the ages of 40 to 50 years. . . . Among the first patients with general paresis, described by French psychiatrists, were many former soldiers and officers of the armies of Napoleon. In these it was speculated that the terrors of war were the precipitating factors. . . . It was not until the trend of investigations shifted from the clinic to the laboratory that the physical causation of general paresis was definitely established. . . . It is of the greatest therapeutic interest that the general paretic who during his illness is inadequately adjusted to his environment—as psychologists call it—becomes following malaria or penicillin therapy a well-adjusted personality without any psychotherapy whatsoever. Physical treatment and not mental healing, that is, talking or lecturing to the patient, relieves the patient of his abnormal behaviour, his emotional disturbances, and his delusions and hallucinations.

If the physical causation of G.P.I. and similar diseases had been known from the beginning, it is doubtful if these would have been classified as psychiatric disorders. It is historical accident, not logical classification, which causes psychiatry to split up into two fields, the medical and the behavioural, which have no underlying connexion with each other, and are as little related as are surgery and epidemiology, or otology and rhinoplasty. It is possible, of course, that the "behavioural" disorders may ultimately be swallowed up in the "medical" ones, and the case of G.P.I. certainly serves as a warning for us not to let speculation run too far ahead of knowledge, and to hold our hypotheses regarding the behavioural, as opposed to the medical, disorders tentatively and not dogmatically. Nevertheless, the distinction appears to be a fundamental one, and in the rest of the chapter we shall be concerned with the methodology appropriate to the "behavioural" disorders, and the main results produced to date by means of modern statistical and experimental methods.

What is the most noticeable and far-reaching difference between the medical and the behavioural disorders? It lies in the absence in the latter of the single "cause" characteristic of the former. In Fig. 1.1, it is the tubercle bacillus which lies at the basis of the whole series of symptoms which characterize the disease. In G.P.I., it is *treponema pallidum* which is the "cause" of all the variety of symptoms displayed. In the behavioural disorders, this single "cause" is absent, and we are left with what in Fig. 1.1 are merely contributory factors—the constitutional ones on the one side, the environmental ones on the other. This crucial difference between the two types of disorder makes it difficult to apply the term "disease" or "illness" to the behavioural disorders; it also necessitates a careful investigation of the appropriate statistical and experimental models to use in this connexion.

As Marzolf (1945) has pointed out—

'There are two ways . . . in which we try to order the phenomena of the natural world and thus explain them. . . . First, we classify phenomena as things or entities which have an invariant conjunction of properties or characteristics. It is this sort of ordering or explanation which is involved in organizing symptoms into syndromes, if and when this can be done. A second kind of explanation is the establishment of causal relations. In this case we likewise search for invariant relations, though they are between antecedents and consequents.

As Degan has pointed out, the first of these kinds of explanation gives rise to two types of analysis.

Each individual or patient may be represented as a collection of the properties or characteristics of his behaviour. . . . The properties or characteristics in this case are the selected symptoms . . . , and the conjunction of these may be viewed either with respect to the individual as a whole or with respect to the relations between symptoms. In the first case, attention is centered on the groups of individuals who display identical, or less stringently, similar symptom patterns. This form of analysis inevitably results in a typology. The other mode of analysis relates each symptom to each of the other symptoms as to their mutual presence or absence, and in this way aggregates of symptoms may be found that display the required conjunction. The components of each of these aggregates are related through some common factor such as being manifestations of the same functional entity, consequent events of the same antecedent or complex of antecedents, etc.

'Invariant conjunctions, as Degan and Marzolf recognize, are rare in biology; the presence of phenylpyruvic acid in the urine is always indicative of mental defect, although even here it must be admitted that mental defect is often present without the secretion. However, "relative conjunction is common in most biological research and is customarily evaluated in the probabilistic terms of modern statistical analysis.

Many . . . factors militate against a strict criterion of invariance. They emphasize the necessity for a statistical interpretation of syndrome formation and suggest the proper form of analysis to be statistical in nature."

As we shall see later, there are two main statistical models which are appropriate to the two types of analysis which Degan distinguishes. If we wish to view the conjunction of symptoms with respect to the individual as a whole, the preferred method of analysis is *canonical variate analysis*. If we wish to view the conjunction of symptoms with respect to their relation

These methods will be discussed in some detail later on; at the moment we must return to the distinction made by Marzoff between "explanation by conjunction" and "explanation by causal relation." These general models have given rise in psychology, and particularly in the study of personality, to two quite distinct schools, which have been named by Brand (1954) the "individual behaviour school" and the "general behaviour school" respectively. Eysenck (1958) has given a succinct presentation of the main differences between these two schools in the form of a Table, which is reproduced below (Table 1.1). As

TABLE 1.1

1. Type of theory	Individual behaviour	General behaviour
2. Aim of theory	Descriptive; cross-sectional	Causal, explanatory
3. Characteristic functions	Static	Dynamic
4. Characteristic assumptions	Non-specificity of behaviour	Specificity of behaviour
5. Characteristic method of analysis	Statistical	Experimental
6. Units of analysis	Traits, abilities, attitudes	$D, sH_R, \dot{I}_R, s\dot{E}_R$, etc.
7. Type of investigation	Inductive	Hypothetico-deductive
8. Type of analysis	Correlational	Functional
9. Relationships analysed	Interdependence	Dependence
10. Statistical paradigm	Factor analysis	Analysis of variance
11. Type of generalization	$\sigma a^2 = \sigma a_1^2 + \sigma a_2^2 + \dots + \sigma a_n^2 + \sigma a_e^2 + \sigma a_i^2$	$sE_R = D \times sH_R$
12. Field of application	Social psychology	Physiological psychology

one to the others, the preferred method of analysis is *factor analysis*. The latter can be used with certain modifications to serve the former aim, as in the case of the analysis of correlations between persons (Eysenck, 1953), but the statistical requirements are too stringent to make this possible in any but exceptional cases.¹

¹ Factor analysis is a method based on Mill's fourth canon, namely that "whatever phenomenon varies in any manner, whenever another phenomenon varies in some particular manner, is either a cause or an effect of that phenomenon; or is connected with it through some fact of causation." If we regard the concurrence of symptoms as covariation we may express it in terms of coefficients of correlation. Factor analysis then proceeds to find a solution for the minimum number of factors or parameters which can adequately account for all the experimentally obtained correlations. Among the assumptions made by this method of analysis is that the initial measures can be described as *linear functions* of the factors, an assumption which gives reasonable first approximations when the variables are monotonic functions of each other. In mathematical terms, what we do is to determine the rank of the correlation matrix; we end up with a system of n vectors in an r -dimensional space, where each of the vectors represents one of the initial variables (symptoms) and r is the number of factors. The correlations between the symptoms are given by the scalar products of the respective pairs of vectors. Factors so derived are seldom psychologically meaningful, and often require *rotation*; this leaves invariant the factor space and the positions within it of the variables, but changes the reference axes. (Thurstone, 1947; Burt, 1940; Thomson, 1939).

Canonical variate analysis deals with the relations obtaining between r groups of subjects, whether diagnostic, racial, or established on any other principle whatsoever, as shown on n tests or measures. The problem is the twofold one of establishing the dimensionality of the space required to accommodate the r groups, and of determining their respective positions

was pointed out in the paper from which this Table has been taken, these two approaches should be regarded as *complementary* rather than as *contradictory*; the analysis of interdependence ("conjunction") and the analysis of dependence ("causation") are both not only justifiable but also necessary methods of research in this highly complex and little understood field of psychological abnormality. No dogmatic assertions about the superiority of the one method should blind us to the usefulness of the other. We will return to this argument later on in this chapter.

There appears to be much confusion as to what can or cannot be done with analysis of interdependence, and particularly with factor analysis. Accordingly, a few examples will now be given of studies employing the technique of factor analysis, and illustrating certain misconceptions as well as certain advantages possessed by this method. Only a brief outline will be given; the reader will find detailed discussions of these and a large number of other studies in *The Structure of Human Personality* (Eysenck, 1953).

The first experiment to be discussed is the work of

to each other. The dimensionality of the space required cannot be higher than $r - 1$ or $n - 1$, whichever is the lower, but it may be lower, thus affording us a more parsimonious description. The probabilities of any individual whose test scores only are known and who belongs to any of the groups on which the analysis has been carried out, are also determined. Articles by S. B. G. Eysenck (1957) and H. J. Eysenck (1955) may be consulted for details and references.

Hewitt and Jenkins (1946). Taking their material from routine case histories, these authors studied five hundred problem children, the average age of whom was between 11 and 12, and the mean I.Q. 94. Forty-five traits were taken from the case histories, and inter-correlations calculated by means of tetrachorics. A cluster analysis was then performed (this is a simplified form of factor analysis), which revealed three factors or clusters of intercorrelated traits. The first one was

parental rejection goes with unsocialized aggression, parental negligence with socialized delinquency, and parental repression with over-inhibited behaviour. These correlations are all relatively high and clearly significant (cf. also Lorr and Jenkins, 1953; Jenkins and Glickman, 1946; Lewis, 1954).

TABLE 1.2

	Unsocialized aggression	Socialized delinquency	Over-inhibited behaviour	Number of cases
Parental rejection . . .	0.48 ± 0.07	0.02	- 0.20	101
Parental negligence . .	0.12	0.63 ± 0.07	- 0.17	78
Parental repression . . .	0.10	- 0.12	0.52 ± 0.06	106

FIG. 1.2. PLOT OF FACTOR LOADINGS OF NINETEEN TESTS AS RELATED TO VARIABLE "EARLY WEANING"

(From Goldman-Eisler, 1948)

called "unsocialized aggressive behaviour"; the second was called "socialized delinquency behaviour"; and the third cluster was labelled "over-inhibited behaviour." Corresponding to these clusters of traits on the *child behaviour* side, there were three clusters on the *parental behaviour* side which were discovered in a similar manner. These three clusters were called "parental rejection," "parental negligence," and "parental repression." Having obtained these clusters on both the child behaviour and parental behaviour side, Hewitt and Jenkins now turn to their main hypothesis: "Children who differ from each other in expressing fundamentally different patterns of behaviour of maladjustment. . . must have experienced fundamentally different patterns of environmental states; and conversely, children who are exposed to such fundamentally different patterns of situation, will exhibit fundamentally different patterns of maladjustment." Proof for this hypothesis is offered in the form of a table of correlations (Table 1.2) which shows that

The second study to be mentioned is the work of Goldman-Eisler (1948, 1950, 1951). She has made an attempt to investigate the concepts of oral pessimism and oral optimism advanced by Abraham (1916, 1924, 1942), and Glover (1924, 1925). "Oral character traits are assumed to originate from repressed or deflected oral impulses which are determined during the nursing period, and which have undergone transformation into certain permanent behaviour patterns by the process of reaction formation, displacement, or sublimation. Two main syndromes of bipolar significance seem to emerge from Abraham and Glover's studies . . . the basic conditions for the development and fixation in character of one or the other syndrome are assumed to be the experiences of gratification or frustration attached to the oral stage of libido development." On the one hand, we have the orally gratified type, which is described by analytic writers as being distinguished by imperturbable optimism, generosity, bright and sociable social conduct, accessibility to new ideas, and ambition accompanied by sanguine expectation. On the other hand, the orally ungratified type is characterized by a profoundly pessimistic outlook on life, sometimes accompanied by moods of depression and attitudes of withdrawal, a passive, receptive attitude, a feeling of insecurity, an ambition which combines an intense desire to climb with a feeling of unattainability, a grudging feeling of injustice, sensitiveness to competition and dislike of sharing.

Fig. 1.2 shows the result of a study in which self-rating scales for nineteen traits, each containing between six and ten items, were administered to one hundred and fifteen adult subjects and intercorrelated. Also included is another item, "early weaning" which was defined as "having been weaned not later than at the age of four months." It will be seen from the figure

that the first factor to emerge from the analysis corresponds in broad outline to the hypothetical oral pessimism oral optimism factor, and that "early weaning" has a significant loading on oral pessimism. The second factor is irrelevant for our discussion here.

The third study to be considered was carried out by Eysenck and Prell (1951, 1952). Seventeen objective tests of neuroticism were given to fifty monozygotic and fifty dizygotic twins, all of whom were normal "in the sense of never having been patients at a Child Guidance Clinic, or in any other way suspected of mental disorders." The same tests were given to a group of twenty-one neurotic children, similar in age and intelligence to the normal twins. The factorial analysis of the intercorrelations of the tests for the normal children gave rise to a very clearly defined factor of neuroticism, and when factor scores were calculated on this factor, for the "normal" and the "neurotic" children, the two distributions were found to be differentiated at a very high level of significance ($p < 0.001$). A diagrammatical representation of the distribution of scores equated for a number of cases is given in Fig. 1.3.

On the hypothesis that neuroticism is inherited, we would expect factor scores on neuroticism to be much more alike in monozygotic twins than in dizygotic ones, and this deduction was in fact borne out. The intra-class correlation between monozygotic twins was 0.851; that between dizygotic twins 0.217. Calculation of Holzinger's h^2 , which is presented by him as an estimate of the degree to which a given score is determined by hereditary factors, shows that $h^2 = 0.81$. While Eysenck and Prell are somewhat critical of this statistic, in view of the fact that some of the assumptions involved in its derivation are clearly not fulfilled in actual practice, there can be no doubt about the significance of the difference between the intra-class correlations in the two types of twins, establishing the fact that hereditary influences play a strong part in this field.

Having presented these three studies as examples of factor-analytic work in the field of personality abnormality, we must now proceed to a discussion of the logic underlying the argument. In so far as the three studies are concerned with the analysis of interdependence, and the isolation of factors, they clearly make a useful and valuable contribution. Subject to replication, these experiments demonstrate the existence of consistent response patterns of various kinds. We are on somewhat less secure ground when dealing with the question of interpretation. The names given to their clusters of factors by Hewitt and Jenkins are purely descriptive, and most readers of the detailed account that they give would probably agree that the terms are well chosen. In the case of Goldman-Eisler, the name chosen is probably somewhat question-beg-

ging, because it assumes that the pattern of correlated traits is in fact determined by early-weaning experiences. One might offer as an alternative hypothesis that the factor she has unearthed is nothing more than extraversion-introversion; indeed it will be noticed that among the items having high saturation on this factor are *endocathexis* and *exocathexis*, which appear to be simply the Greek equivalents of extraversion and introversion. In the case of the Eysenck and Prell

FIG. 1.3. OBJECTIVE Tefi DISCRIMINATION BETWEEN NORMAL AND NEUROTIC CHILDREN

X 2 sets of normal twins are respectively 8 and 14 times the neurotic S.D. removed from the neurotic mean, so that their proper scale positions would fall outside the limits of this diagram.

(From Eysenck and Prell, 1952)

study it will be noticed that the factor is designated as one of "neuroticism," not only because of theoretical considerations or an inspection of the tests defining it, but mainly because of the experimentally demonstrated ability of the factor score to differentiate groups of normal and neurotic children. Such independent evidence regarding the nature of a factor has always seemed to the writer an indispensable part of the process of factor identification, and has indeed been made the basis of a special method of analysis called "criterion analysis" (Eysenck 1950).

It will be noted that the various authors of the papers here considered go beyond the analysis of interdependence, and believe that their work throws some light on the analysis of dependence as well. This is illustrated in Figs. 1.4 and 1.5 which depict diagrammatically the hypothesis underlying the Goldman-Eisler and the Eysenck and Prell study. (A similar diagram could also have been drawn for the Hewitt and Jenkins study.) It is important to consider the logic of this extension of the factor-analytic method because it does not appear to be justified in many cases. Let us first consider the kind of argument presented by Hewitt and Jenkins, or by Goldman-Eisler. This is illustrated in Fig. 1.6. In this figure P refers to the

parental generation, F to the filial generation, x to a certain parental practice, and y to a certain filial practice. A single arrow denotes the use of a given practice by given representatives of a certain generation, while a double arrow denotes causation. The theories of Hewitt and Jenkins and Goldman-Eisler are illustrated in part *A* of Fig. 1.6. Put in words we get this kind of argument: Parents (P) practice early weaning (x); children (F) are aggressive (y) therefore early weaning causes aggression ($x \rightarrow y$). This argument clearly has no logical validity at all; there are many

immediately seen to be untenable. It is one of the first lessons a student of statistics learns that *correlation does not imply direct causation*, and must not under any circumstances be so interpreted without *additional experimental proof*. It is curious that psychologists, almost without exception, have thrown this principle overboard and have interpreted the usually quite low correlations actually found as proof of environmental hypotheses without even considering hereditary or reactive hypotheses. This is all the more astounding

FIG. 1.4. DIAGRAM ILLUSTRATING THE ORIGIN OF A PSYCHOLOGICAL SYNDROME DEPENDENT ON ENVIRONMENTAL FACTORS

FIG. 1.5. DIAGRAMMATIC REPRESENTATION OF A PSYCHOLOGICAL SYNDROME DEPENDING MAINLY ON CONSTITUTIONAL FACTORS

other alternative hypotheses which account equally well for the observed facts. One alternative hypothesis has been illustrated in Fig. 1.6, *B*; this may be called the hereditary theory. Using the same facts as before we may argue that aggressive parents wean their children early, and that the children inherit the parents' aggressiveness. Therefore, parents' aggressiveness is the genetic cause of the behaviour of the children, and x , the weaning behaviour of the parents, is irrelevant and supererogatory as far as the causal relations are concerned.

The second alternative hypothesis can be called the reaction theory. This is shown in Fig. 1.6, *C*, and again makes use of the same facts. According to this hypothesis, aggressive children behave aggressively to their mothers, reject the breast, etc. They therefore cause their mothers to wean them early. The origin of the child's aggressiveness is left indeterminate in this case; his early weaning is caused by his aggressiveness rather than the other way about.

Many other possibilities could be envisaged, but these two will suffice to show that the known facts cannot be used to support the environmental theory in any unequivocal manner. Essentially, the facts offered are *correlational*. A certain type of behaviour on the part of the parent is shown to be correlated with a certain type of behaviour on the part of the child. This is almost universally interpreted as proof of causation by modern psychologists with a bias in favour of environmental determination of behaviour, but once it is realized that we are simply dealing with correlation and nothing else, this assumption is

as the same battle was fought out over thirty years ago in relation to intelligence. It will be remembered that the correlation between parental and familial intelligence was interpreted as evidence of the importance of *environment* by environmentalists and as evidence of the importance of *heredity* by hereditarians, until it was finally realized that the *fact* of a correlation of

- | | | |
|-----|--|-------------------------|
| (A) | $P \rightarrow x$ | ENVIRONMENTAL
THEORY |
| | $F \rightarrow y$ | |
| | $\therefore x \rightarrow y$ | |

FIG. 1.6. THREE DIFFERENT TYPES OF THEORY TO ACCOUNT FOR BEHAVIOUR RESEMBLANCES BETWEEN PARENTS AND CHILDREN

this kind was quite neutral with respect to the *causal explanation* favoured. Such an explanation must receive proof along quite different lines if it is to be acceptable.

What has been said here about the Goldman-Eisler study is, of course, equally true of the Hewitt and Jenkins one. There also the environmentalist hypothesis has been accepted unquestioningly, although

the data do not enable us to choose between it and the "heredity" and the "reaction" hypothesis. It is possible that all the theories are correct up to a point, and even interaction factors may have to be considered.

How do these considerations affect the Eysenck-Prell study? The answer appears to be that here we have an attempt to go beyond the simple analysis of

given elsewhere (Eysenck, 1957, and to be published) of the difficulties involved in causal research of this kind, and of the good points and imperfections of the models currently offered to psychologists by geneticists and environmentalists. For a further discussion the reader must refer to the chapter on genetics in this book.

FIG. 1.7. POSITION OF ONE NORMAL AND SIX NEUROTIC GROUPS IN TWO-DIMENSIONAL FRAMEWORK DETERMINED BY CANONICAL VARIATE ANALYSIS OF OBJECTIVE TEST PERFORMANCES

interdependence and arrange an experiment in such a way that an answer becomes possible regarding the actual determination of the result by heredity factors. This, it will be remembered, was done by employing a research design featuring monozygotic and dizygotic twins. It is only this additional and vital step in the experimental procedure which makes it possible to draw any kind of conclusion from the results with respect to causation. A detailed discussion has been

These three examples have served as an introduction to the application of factor-analytic technique, and they have also revealed some of the difficulties which arise in research of this kind. We must now turn to its application in the wider field of the psychotic and neurotic disorders in general, and to a discussion of the main changes in our thinking which are required when we give up the psychiatric notion of the classical syndromes as *disease entities* and accept instead the

factor-analytic notion of *dimensions of personality*. An example may illustrate the difference, as well as the relation between the two notions. The concept of *hysteria* as a disease entity, analogous to tuberculosis in Fig. 1.1, implies: (i) a single "cause" responsible for the symptoms observed, (ii) a homogeneity of all persons so diagnosed which sets them off qualitatively from all persons not so diagnosed, and (iii) a specific cure applicable to this "disease." The concept of hysteria in dimensional terms is illustrated in Fig. 1.7; this Figure summarizes research data to be presented in

concept extraversion-introversion objectively, and to measure a given subject's standing on the continuum.

The differences between this model and the psychiatric one will be obvious. Instead of a variable number of disease entities, differing from psychiatrist to psychiatrist, and diagnosed only with low reliability, we have two dimensions along which every person can be ranged and given a numerical score. *Continuity* is thus substituted for *discontinuity*¹, and *measurement* for *discrete classification*. The large number of neurotics which on the existing scheme of classification turn

detail later on. According to this diagram, normal and abnormal subjects are distributed with respect to behaviour and test performance over a two-dimensional continuum or factor space. One of the two continua or factors is called "neuroticism," the other "extraversion-introversion." A person who is high on neuroticism and high on extraversion will show a distinct tendency to be labelled "hysteric" or "psychopath" by an examining psychiatrist, while a person who is high on neuroticism and high on introversion will more likely be labelled "anxiety state" or "reactive depressive." The group of introverted neurotic symptoms has been labelled *dysthymia* by the writer (1947), and will be so designated throughout this book. A person high on neuroticism and intermediate with respect to extraversion-introversion is most likely to be labelled "mixed neurosis." An operational definition would, of course, be required of the dimensions involved: Table 1.3 shows some of the objective tests which would be used to define the

out to combine features from several diagnostic categories, or have to be lumped together as "mixed" in their symptomatology, are accommodated as easily in the dimensional scheme as are the "typical" but rare hysterics and dysthymics. Lastly, the scheme implies testable relations between hysterics and psychopaths, on the one hand, and normal extraverts on the other; or between anxiety states and reactive depressives, on the one hand, and normal introverts on the other. Shifts from one diagnosis to another, which should not occur on the hypothesis of discrete disease entities, are easily accommodated in the dimensional scheme if the facts demonstrate shifts along one dimension or the other in the course of time, or as the consequence of specific experimental or therapeutic manipulation. Indeed, as will be shown in later chapters, personality theories can be elaborated which predict such shifts on the basis of drug administration, brain operation,

¹ For attempts to prove experimentally and statistically the continuity hypothesis, see Eysenck (1950; 1952).

and other variables. The advantages of the dimensional system are considerable, and it may be noted that few psychiatrists are in fact willing to defend the old "disease entity" conception except in terms of its historical usefulness. Its early demise will be of considerable help in clearing the field and disabusing the minds of research workers of outmoded and erroneous notions. 1) *Advantages of Statistical model*

(There are many other advantages in explicitly adopting the statistical model associated with dimensional analysis. It enables us to do consciously and deliberately what psychiatrists have usually been doing unsystematically and haphazardly. A syndrome is fundamentally a statistical notion based on covariation; it seems obvious that its derivation will be placed on more secure grounds when it is carried out (i) on the basis of a properly formulated model, (ii) with awareness of the statistical requirements and difficulties involved, (iii) on the firm foundation of quantitative measurement of objective test performance, (iv) in relation to properly selected samples of the population in question, (v) in accordance with the rules of significance widely accepted in biological statistics. It is not implied that the syndromes isolated by psychiatrists in the last hundred years or so are inevitably imaginary and to be discarded; it seems more likely that such consensus as there is points to important and fruitful dimensions which could be validated by proper statistical research, and perhaps improved and sharpened. What does require discarding are the erroneous implications of "disease entities" implicit in psychiatric diagnoses, and the tacit assumption that subjectivity in the creation of systems of classification is a virtue. The psychiatrist typically bases his view on unsystematic observations of small and accidental samples of an undefined population; these observations are then integrated in accordance with unformulated canons of procedure along lines open to the influence of bias and preconceived opinion, and not subject to external safeguards and checks. No verification or duplication is possible, because none of the steps taken are made public; indeed, they are mostly inaccessible to the very person who is carrying out the analysis. It is not clear what assumptions are made, and no attempt is made to see whether the assumptions which appear to be implied are in fact justified. No doubt the psychologist working in the field also makes assumptions and commits errors; however, his assumptions are usually explicit and subject to experimental check. Even when they are not explicit, they can be deduced from the model, and another model substituted if the original one should prove to be contradicted by the facts. If he commits errors of sampling, of testing, of deduction, or of any other kind, these can be detected and corrected because the whole chain of argument and experiment is public and open

to inspection. 'The "subjectivity" of the psychiatrist is often praised as likely to give rise to good hypotheses; this is possible, but science requires also a stage of verification, and this stage has no use for non-objective methods of proof or argument, or for purely subjective *obiter dicta*. Science permits the investigator the greatest amount of freedom in *choosing* his hypotheses, but science also leaves little freedom in *proving* his hypotheses.)

Much of what is said below with reference to the reaction patterns or factors isolated in empirical work by psychologists should be read in this context. Psychiatrists often point to the fact that factors are found which vaguely correspond to common diagnostic groupings, adding that nothing new has been contributed by the experimental and statistical work. This is incorrect. Some psychiatric hypotheses are supported, others are invalidated; it could not have been predicted beforehand which hypotheses would fall into which category. The writer's own work has supported Jung's typology, but not Kretschmer's; it could have been the other way round. There are so many psychiatric hypotheses, systems and syndromes that some of them are almost certain to be right; this does not mean that the task of deciding which in fact correspond to reality is one of supererogation. Furthermore, what was before mere surmise now has acquired operational definition and empirical standing; we can build on this newly acquired, firm foundation where previously there was nothing but shifting sand. Even so, it is not claimed that more has been done by experimental psychology than to make a beginning; with all its faults and crudities, this beginning contrasts with what went before in showing the essential feature of scientific work, namely, that it is *self-correcting*. Even if all the conclusions so far reached should turn out to be wrong, we would at least have the possibility of *proving* them to be wrong. This has never been possible with the traditional psychiatric approach.

In our survey of empirical studies, it will be useful if we begin with a brief summary of the main conclusions to which the evidence seems to lead. This is perhaps unusual, summaries by custom appearing at the end of a survey, but it will be found that the material under discussion is much more easily understood in terms of such a summary. The following then, are the main points to emerge: (i) There are two main, independent factors in the psychiatric field, associated with the *psychotic* and *neurotic* disorders respectively; these will be called *psychoticism* (P-factor) and *neuroticism* (N-factor). (ii) Both factors define continua which range all the way from extreme disorder to normality; there are no breaks or qualitative differences which would enable us to classify people into separate groups. (iii) Introversion-extraversion

TABLE I.4

ITEM SHEET ANALYSIS: VARIABLES INCLUDED IN THE FACTOR ANALYSIS

Number of items in Factor Analysis		
1		Age (16-39) v. (40-59)
2		Psychotic v. non-psychotic (i.e. neurosis and personality disorders)
3	Family History of Psychiatric Disorder	Family history of psychosis
4		Family history of neurosis
5		Family history of abnormal personality (e.g. psychopathy, alcoholism)
6		Unsatisfactory early life
7		Unsatisfactory adolescent adjustment
8	Previous Adjustment	Work position falling and/or frequent unemployment due to instability of patient
9		Lacks confidence when in society
10		Unsatisfactory home life as an adult
11		Neurotic traits in childhood
12		Hysterical symptoms, lifelong or episodic
13	Previous Symptoms	Obsessional symptoms, lifelong or episodic
14		Anxiety symptoms, lifelong or episodic
15		Definite mood variations before present illness
16		Energy output low, lacks effort for success and achievement
17		Symptoms of over 12 months' duration before admission
18	Causes and Onset of Illness	Gradual onset of illness
19		Constitutional causes important or dominant
20		Precipitating psychological and social (environmental) causes unimportant
21		Functional disturbances in systems other than the nervous
22		Retarded activity
23		Overactive, excited, manic or hypomanic, non-manic euphoria
24		Agitated
25		Impulsive and/or aggressive
26		Socially withdrawn
27		Compulsive acts and/or obsessional thoughts
28	Symptoms of Present Illness	Motor disturbances (e.g. posturing, grimacing and catatonic disturbances)
29		Depressed
30		Anxious
31		Mood disturbances (inappropriate or rapidly changing)
32		Suspicious
33		Irritable
34		Suicidal feelings, intentions or serious attempts
35		Schizophrenic type of thought disorder
36		Psychogenic impairment of thought or memory
37		Delusions of guilt, self-reproach, unworthiness
38	Outcome in Hospital	Ideas of reference
39		Delusions (other than those included in 37 and 38)
40		Hallucinations
41		Severe insomnia at any time during illness
42		Gross disturbance of weight and/or food intake
43		Hypochondriacal attitude towards illness
44		Denial, indifference or unawareness of symptoms
45		Recovered or much improved at time of discharge

(I-factor) emerges as a third, independent factor which interacts with neuroticism in the manner suggested in Fig. 1.7, and possibly also with psychoticism. (iv) Intelligence is a fourth factor relatively independent of the other three, but interacting with all of them in complex and almost certainly non-monotonic ways. (v) When psychoticism is studied in isolation, several subfactors are discovered which are usually non-orthogonal and roughly correspond to traditional psychiatric groupings. These may be in part the projection into the psychotic dimension of neuroticism,

intelligence, and extraversion-introversion.¹ (vi) Results are similar whether use is made of factor analysis or canonical variate analysis, and whether the material analysed consists of questionnaires, ratings, or objec-

¹ There is no evidence for the existence of a schizothymia-cyclothymia dimension as posited by Kretschmer (Eysenck, 1950, 1952). This is in good agreement with the genetic evidence, as shown in the chapter by Shields and Slater. There are however systematic differences in *inclusiveness of thinking* between patients diagnosed as schizophrenics and patients diagnosed as (endogenous) depressives (Eysenck, 1960); cf. the chapter by R. W. Payne in this book for a summary of the evidence.

tive personality tests. (vii) Distribution of individual scores on these factors reveals that no clusters corresponding to psychiatric disease concepts such as hysteria or schizophrenia exist; all distributions are continuous and without the clustering predicted in terms of any such theory. (viii) Descriptively, factor scores give a much more detailed and much more accurate picture of individual patients than does psychiatric diagnosis. (ix) Individual persons tend to have scores on all factors, not just on one; this shows the customary practice of allocating a patient to just one diagnostic group to be erroneous. Multiple diagnoses are more

in accord with reality, but still less accurate and less descriptive than factor scores. (x) Some symptoms are more useful for factor measurement than others because they are relatively univocal; some, like "depression," have equally high loadings on several factors and consequently raise special difficulties of scoring.)

We must now turn to a detailed consideration of some of the more important studies in this field, using factor analysis or canonical variate analysis. These will be taken seriatim and labelled according to the person or group of persons responsible for the given study or set of studies.

The Trouton-Maxwell Study

This experiment by Trouton and Maxwell (1956) makes use of an item sheet filled in by the psychiatrist responsible for the patient and which details the presence and absence of a large number of symptoms and traits, there being over five hundred items, intended to cover every psychiatrically significant aspect of the patient's history, symptoms and course of illness.

the presence of several misprints in the original article.)

Our main interest is in factors 1 and 2 which are shown in Fig. 1.8. These are clearly identifiable as *neuroticism* and *psychoticism* by virtue of the items defining each of the two factors; Trouton and Maxwell have no hesitation in labelling them accordingly. Factor 3 opposes schizophrenic symptoms (positive

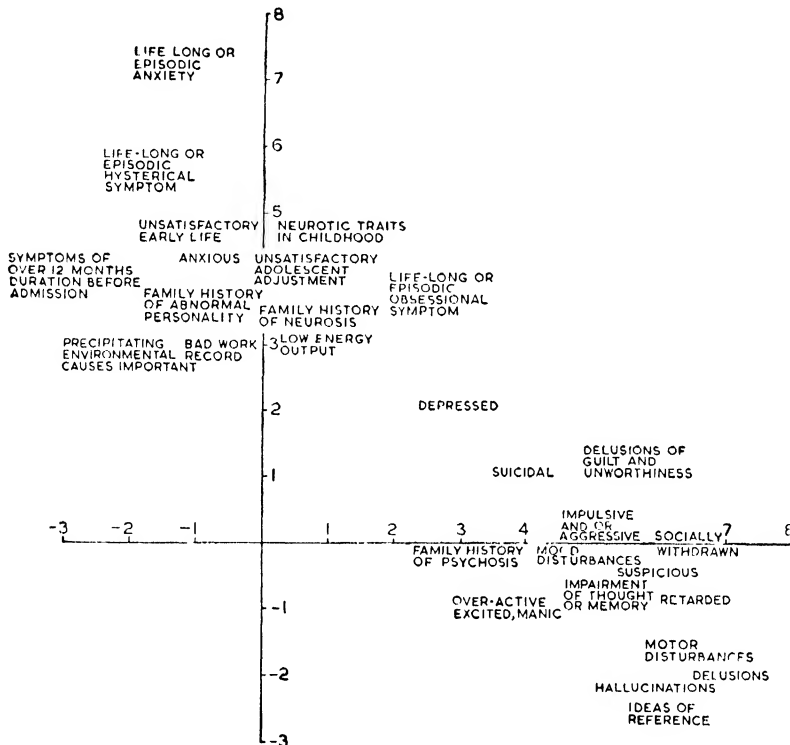

FIG. 1.8. ITEMS DEFINING NEUROTICISM AND PSYCHOTICISM FACTORS

Eight hundred and nineteen male patients aged between 16 and 59 inclusive, were selected at random from the population of The Maudsley and Bethlem Royal Hospitals, care being taken that all organic disorders were excluded. Forty-five items were selected from the total number, mainly on the basis of excluding items having such low frequencies that tetrachoric correlations could not be calculated for them. The forty-five items used are listed in Table I.4. Correlations were calculated between these items and a factor analysis carried out. Six factors were extracted and rotated with retention of orthogonality. The rotated factor matrix is given in Table I.5. (This table differs in some respects from that given in the original article; this is due to the omission of minus signs and

loadings) to symptoms characteristic of psychotic depression (negative loadings) and is, therefore, identified by Trouton and Maxwell with the well-known division in the psychotic field originated by Kraepelin and Bleuer. Factor 4 is labelled by Trouton and Maxwell as one of "inactivity-withdrawal." "Although not as well established as the preceding factors, the continuum is not only semantically satisfactory, but necessary to supplement other factors if some of the different variates of depression and schizophrenia are to be described." "The remaining factors contribute little to the variance and are probably unimportant. Five may represent hypochondriasis and six obsessionalism (the latter is also descriptive of some of the features associated with involutional melancholia).

TABLE I.6

Diagnosis	Psychotic +										Psychotic -									
	N+					N-					N+					N-				
	S+		S-			S+		S-			S+		S-			S+		S-		
	U+	U-	U+	U-	U+	U+	U-	U+	U-	U+	U+	U-	U+	U-	U+	U+	U-	U+	U-	U+
Schizophrenia	6	9	1	2	5	18	0	1			1	1	0	0	1	3	2	0		
Mania	0	0	2	2	0	3	1	2			1	0	0	1	0	0	1	2		
Depression	1	3	5	3	1	0	7	1			0	0	1	2	1	0	2	4		
Involucional melancholia	0	0	4	2	0	0	6	9			1	0	0	0	0	0	0	1		
Paranoia	0	0	0	0	0	6	1	1			0	0	0	0	0	2	0	0		
	T = 102										T = 27									
Anxiety neurosis	1	0	1	1	0	0	1	2			2	2	2	4	1	4	2	7		
Hysteria	1	3	1	2	0	1	1	0			0	4	3	5	1	10	2	1		
Neurotic depression	1	0	0	0	0	2	1	2			0	2	1	1	0	4	6	11		
Pathological and immature personality	2	0	0	0	1	6	0	0			4	15	0	1	2	8	0	2		
	T = 30										T = 107									

There are, however, too few items with loadings on these factors for either of them to be identified with conviction."

It may be of interest to know just where in the dimensional system generated by this analysis patients

of various orthodox diagnostic categories may be found. Table I.6 gives such a tabulation for two hundred and sixty-six unselected consecutive admissions at the Maudsley Hospital. On the left are nine diagnostic groups, divided into psychotic at the top and

FIG. 1.9. POSITION OF VARIOUS CLINICALLY DIAGNOSED GROUPS OF NEUROTICS AND PSYCHOTICS IN TWO-DIMENSIONAL FRAMEWORK PROVIDED BY CANONICAL VARIATE ANALYSIS OF SYMPTOM RATINGS

neurotic at the bottom; on the right side of the table are numbers of patients in these groups falling into each of the sixteen categories produced by dichotomizing the first four factors. Thus, there are six schizophrenics who have an above mean score on psychoticism, neuroticism, schizophrenia and under-activity. Conversely, taking the last figure in the same row, there are no schizophrenics who are below the

is the mean factor score on these two dimensions of groups of patients. The oblique line running across the diagram gives a complete separation of the neurotic diagnoses and the psychotic diagnoses. There are many points of interest in this diagram, the most obvious one being perhaps that while the psychotic groups all have higher psychoticism scores than any of the neurotic groups, the psychotic groups also tend to

FIG. 1.10. PSYCHOMETRIC PROFILES OF THREE PATIENTS, PRESENTING THEIR SCORES ON FOUR FACTORS DETERMINED BY FACTOR ANALYSIS

mean on psychoticism, below the mean on neuroticism, depressive (at the negative pole of the schizophrenia-depression dimension), and overactive. It will be seen that there is reasonable agreement between the factor scheme and the diagnostic scheme, although even in this very rough form of the dimensional scheme, much more information is given than would be the case if each patient were only categorized by a single diagnosis.

Fig. 1.9 gives in diagrammatic form the position of various diagnostic groups in relation to neuroticism and psychoticism. What has been plotted in each case

have high scores on neuroticism, although not on the whole quite as high as the neurotic groups. We shall come back to this point later on.

Table 1.7 and Fig. 1.10 give in diagrammatic form the individual scores of seventy neurotic patients, thirty psychotic patients and twenty normals. The picture is very similar to that given in Fig. 1.9. Nearly all the psychotics have higher psychoticism scores than the neurotics, but while the neurotics tend to have higher neuroticism scores than psychotics, there is no doubt that psychotics on the whole also have elevated scores on neuroticism. Normals, as might have been

expected, are very low on both neuroticism and psychoticism. There are two neurotics labelled *A* in the diagram whose scores fell well into the psychotic group; on readmission to the hospital these were re-diagnosed as psychotic. There is one psychotic patient marked *B* whose score falls well into the neurotic group; on readmission he was re-diagnosed "neurotic."

TABLE I.7
FACTOR ALLOCATION
Analysis by Symptom Pattern Score. Comparison with
Psychiatric Diagnosis

Diagnosis	Normal	Neurotic	Psychotic	Total
Normal (×) .	19	1	0	20
Neurotic (•) .	2	<u>60</u>	8	70
Psychotic (△) .	0	4	<u>26</u>	30
	21	65	34	120

The possibilities of dimensional description as opposed to those of orthodox diagnostic procedures are illustrated in Fig. 1.11, where the scores of three patients (one anxiety neurotic, one agitated depression, one schizophrenia) have been plotted with respect to the first four factors. The patterns are quite distinct and probably more informative than any diagnostic label could hope to be.

The Eysenck Canonical Variate Studies

The Trouton-Maxwell study made use of psychiatric ratings and employed the technique of factor analysis. There are obvious objections to both. Ratings are invariably highly subjective and may reflect nothing but the bias and prejudices of the rater. The authors argue strongly against the possibility that their results could be explained in these terms, but while their arguments have force, they nevertheless cannot completely eliminate this possibility. In a similar way the technique of factor analysis can be criticized in its application to data of this kind which are unlikely to meet the underlying assumptions of this technique completely, and may indeed make it quite inapplicable. It is fortunate, therefore, that we have available two studies using objective, quantitative tests applied to normal, neurotic and psychotic individuals, and employing the technique of canonical variate analysis. If the results of such different studies should be similar to those of the Trouton-Maxwell study, then we can have much greater faith in the accuracy and validity of both.

The first of these studies, carried out by H. J. Eysenck (1955) employed twenty normal, twenty neurotic and twenty psychotic subjects. The tests used were measures of visual acuity, object recognition, mental speed and visual accommodation. The technique of discriminant function analysis used for the study is very much like that of analysis of variance, but being in matrix form requires the calculation of several matrices. First, the total product-sum matrix (*G*) was computed for the four variables, then the between-groups product-sum matrix (*B*), the difference

Fig. 1.11

between these giving us the within-groups product-sum matrix (W). (The latter was checked by an independent procedure). Hamilton (1950) and Rao and Slater (1949) in their analyses, proceeded to maximize the general distance function (D^2); Eysenck followed instead Lubin's (1950) method of maximizing the square of the correlation ratio, given by

$$R^2 = \left(\frac{\text{deviance between groups}}{\text{total deviance}} \right)$$

In essence, the problem is this. We wish to find a set of weights in order to derive from our four tests a

ratio (R) between the three groups and the two variates is 0.84, a not unreasonably low figure when the unreliability of the criterion is borne in mind.

As a next step, scores were computed for each subject on both variates. This was done in the following way. The latent vectors furnish us with two sets of weights to apply to the scores, so that two measures can be calculated for each subject, one for each canonical variate. The scores Y_1 and Y_2 were found by multiplying the score of each subject by the appropriate weights and running them over the four tests. A plot of these scores is given in Fig. 1.12, where normals are represented by crosses, neurotics by dots and

FIG. 1.12. VARIATE SCORES AND GROUP SEGREGATION USING VISUALLY FITTED LINES

(From Eysenck, 1955)

composite score for each subject such that the square of the correlation ratio (R^2) between that composite variate and the three groups is at a maximum. Hence, if we take $R^2 = \hat{u}Bu/\hat{u}Gu$, following Lubin (1950), we arrive at the equation $(G^{-1}B - R^2I)u = 0$. (In this expression, G and B have already been defined, u is the column vector of weights and \hat{u} is its transpose. I is the unit diagonal matrix). The values of R^2 which satisfy this equation are the latent roots of the non-symmetric-matrix $G^{-1}B$, each root having a corresponding latent vector u . Obtaining $G^{-1}B$ involves calculating the inverse of the matrix G and post-multiplying it by B . This results in the non-symmetric matrix BG^{-1} from which the latent roots and vector are extracted using an iterative method for non-symmetric matrices. As the rank of $G^{-1}B$ is always one less than the number of groups (or of tests, whichever is the smaller), only two latent roots were found. Both were significant showing that two dimensions are required to account for the differences in test performance between the three groups. The correlation

psychotics by triangles. A rotation of the two variates brings them in line with the Trouton and Maxwell factors, and is shown in Fig. 1.13, where Z_1 corresponds to the neuroticism factor and Z_2 to the psychoticism factor. It will be seen that here again psychotics have high psychoticism scores, but also tend to have high neuroticism scores, while neurotics have low psychoticism but high neuroticism scores. Normals have scores which are low on both factors. Two individuals marked with an A and B respectively were originally diagnosed as neurotic but appeared in the psychotic group. On readmission they were re-diagnosed as psychotic.

A similar analysis but using a much larger number of tests and persons, was carried out by S. B. G. Eysenck (1955, 1956). Working with one hundred and twenty-three normal subjects, fifty-three neurotics and fifty-one psychotics, she used six tests in all (an expressive movement test, a manual dexterity test, a psychogalvanic reflex test, a static ataxia test, a word association test and the Maudsley Medical Questionnaire).

FIG. 1.13. RESULT OF "ROTATION" IN THE CASE OF THE PRESENT CANONICAL VARIATES
(From Eysenck, 1955)

FIG. 1.14. VARIATE SCORES AND GROUP SEGREGATION USING MINIMUM LIKELIHOOD SOLUTION
(From S. B. G. Eysenck, 1956)

She found two significant latent roots, and calculated scores for the individual subjects of her experiments which are plotted in Fig. 1.14. We again note the same state of affairs as previously, namely, that neurotics are low on psychoticism whilst the psychotics are high on not only psychoticism, but also to some extent

now proceed to mention several studies which investigate more closely the subdivision within these great groups. The first of these was carried out by Eysenck (1947), in which thirty-nine symptomatic and descriptive items were intercorrelated for seven hundred neurotic patients. The results are shown in Fig. 1.15;

FIG. 1.15. ITEMS DEFINING NEUROTICISM AND EXTRAVERSION-INTROVERSION FACTORS
(From Eysenck 1947)

on neuroticism. We may conclude, therefore, not only that the two canonical variate studies are in good agreement with respect to their conclusions, but also

FIG. 1.16. CONFIGURATION OF DIAGNOSTIC GROUPS
(From Rao and Slater, 1949)

that they forcibly support the results of the Trouton-Maxwell study.

The Neuroticism and Extraversion-introversion Studies

Having shown the relatively clear-cut distinction between neurotic and psychotic disorders, we must

they support rather strongly Janet's hypothesis of hysterical disorders being opposed to dysthymic disorders. The results also seem to agree with Jung's hypothesis (cf. Fig. 1.3) of hysteria as characteristic of extraverted neurotics and the dysthymic disorders as characteristic of introverted neurotics.

The study just mentioned made use of factor analysis. Another experiment by Mayer-Gross *et al.* (1949) and Rao and Slater (1949), used the technique of canonical variate analysis. Two hundred and one neurotics and fifty-five normal officers were rated psychiatrically on thirteen main behaviour symptoms. These ratings were combined into three scores and canonical variate analysis carried out on these scores for five neurotic diagnostic subgroups and the normal subjects who constituted the sixth group. The results are shown in Fig. 1.16 where it will be seen that the first variate (neuroticism), opposes the normals to the neurotic individuals, while the second variate opposes the hysterics and psychopaths (extraverts) to the dysthymic groups, i.e. the obsessionals and anxiety states

(introverts). The picture is in agreement with the Eysenck study but it should be noted that the second latent root in this study fell short of statistical significance.

Hildebrand (1958) has published a factorial study of the test performances of twenty-five conversion hysterics, twenty psychopaths, ten reactive depressions, ten obsessional neurotics, twenty-five anxiety states, fifty-five neurotics of mixed symptomatology, and a small sample of normal subjects. Twenty-five tests in all were used in this study, including questionnaires, performance tests, and measures of intelligence. Lawley's Maximum Likelihood Method was used for the extraction of factors. Three main factors emerged: neuroticism, extraversion, and intelligence. Factor scores were estimated for neuroticism and extraversion for all the subjects, and it was found: (1) that there were no significant differences among the neurotic population, as far as neuroticism was concerned, but that the normal group differed significantly from the total neurotic group; (2) that with respect to extraversion, "inspection of the means demonstrates clearly that the distribution follows the prediction. The hysterics and psychopaths are clustered at the extravert end of the distribution, and the dysthymics at the introvert end of the distribution, with the mixed neurotics occupying a central position." (Fig. 1.7 illustrates these findings.) Hildebrand also found that the sample of normal subjects used by him was atypical in being highly extraverted on a standardized scale. A more representative sample was substituted, and a canonical variate analysis performed by P. Slater (in Eysenck, 1960). The results of this analysis supported Hildebrand's conclusions on most points, but also added important information with respect to the dimensionality of the neurotic groups included; the data are too extensive, and the discussion too technical to be included here.

Far more impressive and convincing than Hildebrand's data is a more recent study by G. Claridge (in Eysenck, 1960). He based his selection of tests very largely on the experimental literature reviewed in Table I.3, as well as on certain direct deductions from Eysenck's *Dynamics of Anxiety and Hysteria* (1957); this theory was, of course, still in the process of construction when Hildebrand selected his battery of tests. Groups of sixteen hysterics, dysthymics, schizophrenics, and normals, equated for sex, age, and intelligence, were submitted to a very lengthy battery of tests and questionnaires, including measures of reminiscence, vigilance, disinhibition, massed practice effects, time error, time estimation, auditory flutter fusion, body sway suggestibility, rotating spiral after-effects, and tachistoscopic picture recognition, as well as measures of neuroticism and extraversion from the Maudsley Personality Inventory (Eysenck, 1959)

and the M.M.P.I. Precise predictions were made for each test with respect to its differentiating power between groups, and its likely factorial content in a correlational study between groups. The details are too numerous to be reviewed here in detail, but the outcome of the experiment on the whole was strikingly positive. In terms of both factor scores and canonical variate scores, it proved possible to differentiate the extraverted (hysteric) and the introverted (dysthymic) groups without, or with at most one error.

The improvement in efficiency of classification, clearness of outcome, and reliability of prediction from the Hildebrand to the Claridge study demonstrates the importance of theoretical considerations in designing factorial studies, as well as the possibilities of self-correction inherent in the factorial paradigm. It seems likely that an equal gain in clarity and validity will attend the further purification, both theoretical and experimental, of the present battery of tests.

Two further studies should be mentioned in this section. Both deal with the factorial analysis of anxiety and its symptomatology. Their interest arises from the fact that anxiety, from the theoretical point of view, is not a univocal variable but has loadings on both neuroticism and introversion; in other words, it is regarded as a conditioned fear reaction. Neuroticism is conceived of as an inherited autonomic over-reactivity, while introversion is characterized by strong conditionability (Eysenck, 1957); hence anxiety as a conditioned fear reaction appears most frequently in dysthymics, i.e. neurotic introverts. If, now, a factorial study were to be done of anxiety symptoms in patients suffering from anxiety, it should prove possible to separate out these two factors from each other, i.e. to obtain one factor of autonomic over-reactivity, and one characterized by the conditioned anxiety responses.

That this prediction is essentially correct has been shown by O'Connor, Lorr and Stafford (1956), and more particularly by Hamilton (1959). The latter intercorrelated thirteen variables, obtained through ratings made by several psychiatrists, and having reasonably high reliabilities; these were then inter-correlated and factor analysed, giving rise to two factors: (1) somatic anxiety, characterized by gastrointestinal, genito-urinary, respiratory, cardiovascular, and general somatic and autonomic symptoms; (2) psychic anxiety, characterized by tension, fears, insomnia, cognitive changes, depression, behaviour, and anxious mood. These results agree reasonably well with those of O'Connor *et al.*, and are in quite good agreement with its hypothesis. Unfortunately there is no direct study of the most direct deduction to be made from the hypothesis, namely that extraverted neurotics, i.e. hysterics and psychopaths, would be characterized by somatic anxiety, but not by psychic

anxiety. This crucial experiment still remains to be performed.

Psychoticism and its Subdivisions

THE MOORE STUDY (1930; 1933)

This is probably the first to carry out "the empirical determination of certain syndromes underlying praecox and manic depressive psychoses." Three hundred and sixty-seven patients were rated for the presence or absence of forty-one symptoms, tetrachorics were calculated, and the resulting table analysed by a complex and cumbersome procedure. Eight factors in all were isolated; these, on being intercorrelated, gave rise to two "second-order factors" as they would be called nowadays. The first of these two was made up of the catatonic, cognitive defect, uninhibited and deluded-hallucinated syndromes; this appeared to be a *schizophrenic factor*. The second factor was made up of the retarded-depressed, constitutional-hereditary and manic components; this appears identifiable with *circular insanity*.

Thurstone (1947) reanalysed Moore's data with more modern methods and obtained five rather more clearly defined factors. Even more recent is another reanalysis of Moore's original correlations carried out by Degan (1952). He obtains the following main factors: A = hallucination-delusion (hyper-projection); B = depression; C = hyperexcitability; D = catatonia; E = schizophrenic dissociation; F = psychotic shock; G = hyperirritability; H = deterioration; I = neurasthenia.

These factors are themselves correlated and give rise to second-order factors. The first of these second-order factors, factor W, has high loadings on factors G, C and H and (negatively) I. According to Degan "factor W is quite obviously mania and seems to represent predominantly a condition of sustained hyperexcitability." Factor X has high loadings on E, F, A and H; "this factor is consistent with the current conception of hebephrenic schizophrenia and is so interpreted." Factor Y has positive loadings on I and B and negative ones on G and A. According to Degan "Factor Y . . . supports the proposal of a projective-introjective process at the basis of a paranoid-depression classification of psychosis." To the writer it seems possible that this factor may be similar to extraversion-introversion, although the lack of work done with that factor in the psychotic field makes it impossible to substantiate this interpretation. Factor Z has loadings on D, F, G and H, and (negatively) on B; it is interpreted as catatonic schizophrenia.

It is impossible in this brief space to give an adequate discussion or critique of the work of Moore, or the analyses done by Thurstone and Degan. Attention should be drawn, however, to the fact that the same

matrix of intercorrelations gives rise to different numbers of factors, different numbers of second-order factors, and different interpretations of these factors in the three analyses. No criterion is offered for a choice between the different interpretations and it is not always obvious how in fact the interpretations given could be supported or disproved by further experimental work. This is a weakness of the factor-analytic approach which the writer has discussed in detail elsewhere (Eysenck, 1957) and to which attention must be drawn here in order to avoid too great confidence being placed in the results of any particular study.

THE WITTENBORN STUDIES

There are some thirteen studies reported by this author and various collaborators, details of which will be found in the references. What Wittenborn has done in effect is this: he has constructed fifty-five symptom rating scales, carefully drawn up and given in detail in a monograph by Wittenborn, Holzberg and Simon (1953). "The set of rating scales is considered to comprise a good sample of the descriptive aspects of mental hospital patients' behaviour currently considered by psychiatrists to be important in evaluating patients and in making diagnoses. Each rating scale describes only one extreme of a pathological manifestation. The scales are in such a form that they may be checked for every patient in order to reduce bias on the part of the raters, the scales being presented in a randomized, unlabelled manner. In order to minimize systematic differences between raters, due to their theoretical orientation, the scales are primarily descriptive and involve as little interpretation as possible."

These scales have been applied to many different groups of patients and several factor-analytic studies have been carried out. Nine clusters or factors emerge from these analyses, namely: (1) acute anxiety, (2) conversion hysteria, (3) manic state, (4) depressed state, (5) schizophrenic excitement, (6) paranoid condition, (7) paranoid schizophrenia, (8) hebephrenic schizophrenia, (9) phobic-compulsive. The individual items in the original scale are then weighted so that it becomes possible to give each patient a score for each of the nine factors or syndromes. The odd-even reliability scores for these cluster scores are reasonably high, ranging from 0.67 for depression to 0.92 for mania. They are not, however, independent of each other. Thus, for instance, there is a correlation of 0.88 between hebephrenic schizophrenia and schizophrenic excitement. There are several other correlations above 0.6, one of them between acute anxiety and phobic-compulsion (0.67) giving support to the concept of dysthymia. No second-order factor analysis appears

to have been done by Wittenborn, which is unfortunate in view of these high correlations. (It must, of course, be remembered that the intercorrelations among the cluster scores are higher than intercorrelations among the clusters themselves would be; this is the probable result of the use of overlapping items and the rough system of weighting used.)

Wittenborn and Holzberg (1951) have compared the results of their rating scales with the Rorschach test, with the conclusion that "the present analyses cannot be taken as any evidence that descriptive aspects of the behaviour of psychotic patients may be identified with or predicted by a use of Rorschach scores." The same authors made an investigation into the use of the Wechsler-Bellevue score in this connexion and found all correlations with their descriptive rating scales to be very low. In another study Wittenborn and Mettler (1951) have studied the practical correlates of psychiatric syndromes by relating the Wittenborn scales to the kinds of socially practised behaviour observed in occupational therapy situations.

The problem of reliability has been attacked by Wittenborn *et al.* (1952) by having two different samples of patients rated by two different psychiatrists—

In order to maximize any difference in symptom clustering due to differences in psychiatrists, the psychiatrists who provided the ratings were selected in a way calculated to maximize the difference in their rating scales. It was possible to find two psychiatrists who were rating similar patients but who differed in age, cultural background, theoretical bias and training. . . . Clusters revealed by the two analyses were mutually consistent and similar to the clusters which had been found originally in large samples of patients rated by a variety of psychiatrists. The data did not challenge the claim that the qualitative behaviour significance of the cluster scores used in the quantified, multiple diagnosis, is relatively independent of ordinary differences between psychiatrists.

In spite of some contradictory evidence by Pumroy and Gogan (1955), who found relatively low coefficients of concordance between four observers of eleven patients for several of the scales, the data presented by Wittenborn and his colleagues are distinctly impressive, and from the practical point of view there seems to be no doubt that his scales are at the moment the most practical available method for quantitative dimensional description of abnormal behaviour. From the theoretical point of view, however, his failure to carry out a second-order factor analysis, and the relative lack of neurotic subjects and symptoms in his work, make it difficult to accept his conclusions as definitive.

THE GUERTIN STUDIES

There are eleven papers in this series which will be found in the bibliography under his name. Typical of his work is his 1952 "Factor Analytic Study of Schizophrenic Symptoms" in which he studied the intercorrelations between fifty-two symptoms in one hundred schizophrenics between the ages of 16 and 60. He obtained six factors which accounted for 58 per cent of the total variance: (1) excitement-hostility, (2) psychomotor retardation and withdrawal, (3) guilt conflict, (4) persecution-suspicion, (5) personality disorganization, (6) confusion-withdrawal. These factors are not independent; thus confusion-withdrawal correlates 0.49 with psychomotor retardation. Guertin finds that: "Several factors are required to describe most of the individuals in this study."

In some other studies, Guertin makes use of the Ferguson hospital adjustment scale. Working with unhospitalized schizophrenics he concludes that "approximately 63 per cent of the variance of the items samples could be described in terms of three oblique factors"; these he labels: (a) lack of general interest, (b) social withdrawal, (c) personal unconcern. (The correlations between these three factors are quite high, ranging from 0.5 to 0.7.) Guertin believes that his analyses provide some confirmatory evidence for Jenkin's hypothesis of the existence of three schizophrenic types (1952), which will be discussed presently.

Guertin also reports a number of inverted factor analyses, i.e. analyses in which correlations are run between patients rather than between symptoms. This technique, which has been discussed in some detail by the writer (Eysenck 1953) is difficult to justify for this type of material as there does not seem to exist a metric continuum over the different sets of symptoms. While Guertin's work is interesting therefore, it is rather difficult to evaluate. As regards his more orthodox studies it will be noted that the concordance of his results and those reported by Wittenborn is rather small. In part this may be due to differences in the respective samples and the total universe of ratings covered, but as both authors have sought a rather comprehensive coverage, this can hardly be the only reason. Such failure on the part of one author to verify the results of another, must make us doubtful about the validity of the results reported by either.¹

¹ Similar objections apply to the work of Monro (1954, 1955, 1956), who has used R and Q methods of analysis on rating derived from two hundred mental patients. Monro follows in part Cattell's system of classification and analysis, and compares his findings with those of Cattell. In view of the importance and general interest of Cattell's work, it ought perhaps to have been treated here at some length. This has not been done for the following reasons. Cattell has worked almost entirely with normal subjects, and while he often uses psychiatric terminology in naming his factors, there is little independent evidence that this is justified, and that the presumed relationships with mental abnormality do in fact exist. Some recent and as yet unpublished Canadian work by

THE LORR AND JENKINS STUDIES

Jenkins (1952) has suggested a theory which he labels "schizophrenic sequence" and according to which there are three schizophrenic types, namely, the withdrawn, the disorganized and the type characterized by psychotic reorganization. Lorr and Jenkins have carried out several studies in recent years on the psychopathology and behaviour of hospitalized psychotics which may in part be looked upon from the point of view of their theory. In their 1955 article they describe the construction of eighty-one brief descriptive rating scales which were used on four hundred and twenty-three male psychotic patients. By a process of correlational analysis a 55-variable correlation matrix divisible into thirteen clusters was finally selected and subjected to multiple group factor analysis. Eleven factors were extracted and the first-order rotated oblique factor matrix is given as Table 1.8. The authors group the factors for purposes of description and discussion "into those that appear to reflect affective disorders, those that may be considered indicative of schizophrenic processes, and those relating to disturbances of temperament or character which may be observable in non-psychotics as well as in psychotic patients."

Bipolar factor A "is retarded depression versus manic excitement . . . Wittenborn's bipolar manic-depressed factor bears close resemblance to A. Degan's unipolar factor, manic hyperexcitability, is very similar to the positive pole of A." Factor E "appears to be a melancholia-agitation. . . . Degan's 'depression syndrome' . . . resembles E. The agitated depressive picture repeatedly identified by Wittenborn also closely resembles factor E."

Factors I, K and G are related to Jenkins's hypothesis of the schizophrenic sequence. Factor I is regarded as one of *withdrawal* and is said to resemble Degan's factor H. Factor K is said to represent progressive personality *disorganization* and to resemble Degan's factor of schizophrenic dissociation. F and G respectively represent perceptual disorganization (Degan's factor of hyper-projection) and motor disorganization (with a possible resemblance to Degan's catatonia factor).

"An alternative to the pattern of disorganization is paranoid *reorganization* and stabilization . . . factor C appears to be descriptive of this paranoid pattern. . . . Wittenborn's paranoid schizophrenic factor is probably identical with it. . . . Paranoid suspicion is often paralleled or followed by grandiose expan-

siveness that appears to underlie factor J." Wittenborn's paranoid cluster is claimed to resemble J.

"The third group of factors consists of resistiveness (B), submissive versus belligerence (H), and activity level (D) . . . Degan's hyperirritability factor . . . may be the same as H but seems less well defined."

From the intercorrelations of these factors, three second-order factors are derived. The first (AA) denotes "a resistive withdrawal with motor disturbances." The second factor (BB) "appears to be a measure of schizophrenic disorganization, projection and distortion of thinking and perception." The third second-order factor (CC) "is a bipolar continuum of apathetic, confused withdrawal versus agitated hyperactivity." Lorr and Jenkins identify (AA) with Degan's second-order factor Z, (BB) with Degan's factor X, and one pole of the bipolar factor (CC) with Degan's factor W.

In a later study Lorr, O'Connor and Stafford (1956) attempted to verify the existence of the factors described and related them to the Wittenborn scales. They used thirty-nine of their own rating scales and sixteen of the Wittenborn ones, using a total of one hundred and sixteen psychotic patients. A total of fifty-two scales was used for the intercorrelations and the intercorrelations between these scales analysed by means of the multiple group method. The results of the analysis are similar to those reported previously and it is interesting to know that this time a second-order factor, similar to Degan's factor Y, appears. In the study previously mentioned this factor was the only one of Degan's four second-order factors which could not be duplicated.

The identification of factors attempted by Lorr and his colleagues is done entirely on the basis of inspecting the content of ratings having high loadings on each factor. This is known to be a difficult and unsatisfactory method, and it would have been preferable if a more objective technique such as that put forward by Ahmavaara (1956) had been used. However, it should be remembered that in a sense these are all pioneer studies, and that future work will undoubtedly incorporate such obvious improvements as this. As matters stand now, the reader has to form tentative conclusions on the basis of such material as is available, and on this basis the writer would suggest that while there are certain recurring clusters of similar implication running through this work, nevertheless, in most cases no confident identification can be made. This cautious conclusion with respect to the fundamental contribution these studies have to make, should not distract from their practical usefulness in identifying patients showing different reaction patterns. Regarded from this point of view, both scales and classifications are undoubtedly superior to the traditional psychiatric methods and systems.

N. Agnew and B. Craig on Cattell's factors 25 and 29 ("Accurate realism *v.* psychotic tendencies" and "Ready mobilization of energy") failed to find predicted relationships between test scores and psychiatric state, and also between factor score and psychiatric state. This is not necessarily fatal to Cattell's system, but it suggests caution in accepting it in so far as abnormal mental states are concerned.

THE EYSENCK "CRITERION ANALYSIS" STUDY

There is one additional reason why the list of studies reviewed above is less certain and impressive than one might have wished. All the work done was carried out in terms of subjective ratings made by psychiatrists, clinical psychologists and others reared in a tradition which makes a point of regarding certain assumptions and relationships as relatively firmly established. It is possible, therefore, that such modest agreement between different analyses as has been found is nothing but a reflection of the common teaching received by the raters. It would require an experiment specially designed to make use of objective tests exclusively to overcome the inherent subjectivity of any kind of symptom rating schedule. Only one such study has been made (Eysenck 1952). In this experiment one hundred normal, fifty schizophrenic and fifty manic-depressive subjects took part. A large battery of objective tests was administered to the two hundred subjects; out of these twenty were selected for a correlational analysis. The method used was that of criterion analysis (Eysenck 1950) which requires the calculation of correlations separately for the normal and the abnormal group. Factors are then extracted from the two matrices separately. This is done in order to test the interpretation of the factors extracted in terms of the original dichotomy. For details the original publications should be consulted, but putting it very briefly, the argument runs like this: If, and only if, the differences between the normal and the psychotic groups are quantitative rather than qualitative, and the relations between each test and this continuum monotonic, and preferably linear, will the following relationship be obtained. (1) A factor will be found in the analysis of the matrix of correlations for the normal group which is identifiable as "psychoticism." (2) A factor will be found in the analysis of the matrix of correlation for the psychotic groups which is identifiable as "psychoticism." (3) The loadings on one of these factors will be proportional to the loadings on the other. (4) Both sets of loadings will be proportional to a set of index values denoting the adequacy of each test in separating the normal and psychotic groups from each other; the column containing these values is known as the "criterion column." The method of criterion analysis thus enables us to answer two questions simultaneously. It makes it possible for us to see whether or not the groups with which we are dealing are separated from each other on a quantitative or a qualitative basis, and it enables us to interpret the hypothetical factor of psychoticism in a unique and clear-cut fashion.

The results of the study are in good agreement with the hypothesis that psychoticism is a continuous variable responsible for separating the normal and other psychotic groups. The psychoticism factors extracted

from the two groups correlated 0.871, and these two factors correlated with the criterion column 0.899 and 0.954 respectively. A second factor was found in both matrices and it was shown that this also was the same in both groups, the correlation between the two sets of factor loading being 0.768. It was hypothesized that this second factor might be one of schizothymia-cyclothymia, and this hypothesis was also capable of testing in terms of criterion analysis because of the inclusion of the schizophrenic and manic-depressive groups in the experimental design. A new criterion column was formed, based on the differentiating power of the tests as far as the two psychotic groups were concerned, but this was not found to be correlated with the second factor loadings, thus disproving this hypothesis.

This method of criterion analysis, which has also been applied with some success to the neurotic field (Eysenck 1950, 1952) has the obvious advantage of making the interpretation of factors more objective by relating them directly to diagnostic groups. This may appear to assume the correctness of the original diagnostic groupings, but this is by no means the case. Provision is made in the method for maximizing agreement between factor scores and criterion by means of a double process of rotation involving both the criterion and the factors. It is suggested that an application of this technique, together with the use of objective tests, would go far to clear the air of the inherent subjectivity of the more usual type of analysis, a subjectivity inherent not only in the choice of data, but also in the method of rotation.

Most of the studies so far considered would fall under the heading of "individual behaviour theories" in Table I.1; in other words, they are cross-sectional, descriptive, and essentially "static." However true and accurate the dimensional picture presented there might be, it could rightly be criticized for failing to provide a dynamic component, or any indication of *causal* relationships. To know a person's position on a given dimension is one thing; to know the reasons for his being there, and the methods for changing his position, is quite another. We require "general behaviour theories" to give us this type of information, and we require above all hypotheses linking these two types of theory together. As Hull (1945) has pointed out—

The natural science approach to behaviour theory presents two major tasks. The first is to make a satisfactory working analysis of the various behaviour processes; this consists in deriving, i.e. deducing, from the primary laws of the system the characteristic observable phenomena of the behaviour process in question as displayed by the modal or average organism under given conditions. . . . The second major task of the natural science approach to behaviour theory concerns the

problem of innate behavioural differences under identical conditions between different species and between individuals within a given species. . . . Both types of task cry loudly and insistently for completion. But most neglected of all is the relationship between the two approaches.

An attempt to work out such an integration of the two approaches in the general field of abnormal psychology, and more specifically in that of the neurotic disorders, has been made by Eysenck (1957). Fig. 1.17 shows the general outline of the theory proposed to account for extraverted and introverted behaviour

conditioned responses, would also tend to be strongly socialized, while individuals with weak excitatory and strong inhibitory potentials, who would be expected on that basis to form weak and unstable conditioned responses, would also tend to be weakly socialized. The former group would thus tend to develop *introverted* behaviour traits (persistence, high level of aspiration, reliability, etc.), while the latter group would tend to develop *extraverted* behaviour traits (cf. Table I.3). Groups intermediate with respect to the excitation-inhibition balance would also be expected to be

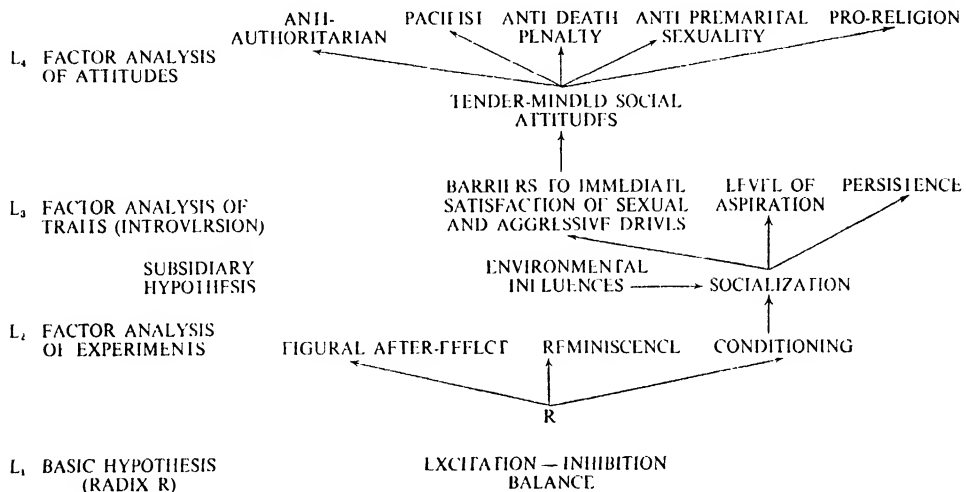

FIG. 1.17. DIAGRAMMATIC REPRESENTATION OF DIFFERENT LEVELS OF PERSONALITY ORGANIZATION AS DETERMINED BY INDIVIDUAL DIFFERENCES IN THE EXCITATION-INHIBITION BALANCE

respectively. At the base of the diagram we have the (presumably innate) balance between cortical excitation and inhibition, using these terms in the molar sense of Pavlov and Hull. Some persons are characterized by a nervous system predisposing them to develop exceptionally strong *inhibitory* potentials; others are characterized by a nervous system predisposing them to develop exceptionally strong *excitatory* potentials. Most people are intermediate between these extremes.

Certain phenomena observable in the psychological laboratory can be deduced from this hypothesis. Thus conditioning, reminiscence, figural after-effects, and many other phenomena are theoretically derivable from the concepts of excitation and inhibition, and consequently individual differences in these phenomena can be deduced from individual differences in the excitation-inhibition balance. If, in addition, we accept Mowrer's (1950) hypothesis that the socialization process depends on conditioning, then, under equal environmental pressure, individuals with strong excitatory and weak inhibitory potentials, who would be expected on that basis to form strong and stable

intermediate with respect to conditionability, and consequently with respect to socializability and extraversion-introversion. This analysis has been extended also to the field of attitudes and opinions (Eysenck, 1954), along the lines indicated in Fig. 1.17.

A causal scheme such as the one here suggested is susceptible of disproof along two lines. It mediates deductions which can be tested by means of analysis of *interdependence*, and it mediates deductions which can be tested by means of analysis of *dependence*. The first type of analysis suggests tests of the predicted relationships obtaining at each level of Fig. 1.17; thus we would predict correlations between the different attitudes at level L_4 , the different traits at level L_3 , or the different experimental phenomena at level L_2 . The second type of analysis suggests tests of the predicted relationships between phenomena at one level and those at another; thus the theory predicts that extraverts (and hysterics) should be less easily conditionable than introverts (and dysthymics), or that introverts should have tender-minded attitudes, extraverts tough-minded ones. Many such tests have been carried out along both lines, and the results have on the whole

supported the general hypothesis (Eysenck, 1957, 1960).

We thus see that "individual behaviour theories" and "general behaviour theories" are not essentially antagonistic, but can be integrated within the confines of a single scheme or system; "general behaviour theories" refer to the vertical type of deduction in Fig. 1.17, "individual behaviour theories" refer to the horizontal type. A complete explanation of any aspect of behaviour requires both types of theory, and both types of analysis.

A similar analysis is possible with respect to neuroticism. Here the hypothetical radix is conceived to be the balance or lack of balance of the autonomic system, i.e. its speed of response, its strength of response, and its persistence of response. The individual high on neuroticism is conceived to be a person with an over-reactive, labile type of nervous system, a person who reacts too strongly, and too persistently to strong external stimuli. (The question of speed of reaction is a difficult one. The evidence does not suggest that the neurotic type of person is quicker to react than the less neurotic person; if anything the opposite is true). The evidence with respect to this generalization has been discussed elsewhere (Eysenck, 1953), and will be reviewed in detail in another chapter in this book. It is by no means conclusive, and certainly less compelling than is the evidence relating to the determination of extraverted and introverted behaviour by the excitation-inhibition balance.

In particular, the work of Lacey and Malmö (cf. Chapter 11 by I. Martin) suggests that over-reactivity is not necessarily a property of the whole autonomic system, but may rather be the property of a particular subsystem. Nevertheless, however much the statement of the hypothesis may require to be qualified, it probably embodies a generalization which carries within itself the possibility of the successful mediation of many testable predictions.

Taking our two hypotheses together, we can certainly deduce the known facts about dysthymic and hysterical symptomatology and behaviour. As an example, let us consider the strong anxiety which is such a pronounced feature of the dysthymic personality. Anxiety may be defined as a conditioned fear reaction, and we would expect (other things being equal) that its strength would be determined by (i) habit strength as a function of the number of reinforcements received ($N \rightarrow {}_sH_R$), and (ii) incentive-reinforcement as a function of amount of reward ($w \rightarrow K$). Given equal amounts of N and w , i.e. equalizing environmental influences, we may substitute greater conditionability for greater N as giving rise to greater ${}_sH_R$, and greater autonomic reactivity for greater w as giving rise to greater K . Hence *under equal environmental pressure*, the person high on introversion and on neuroticism should develop strong con-

ditioned fear responses as compared with persons having any other combination of scores on these two factors, due to his tendency to develop strong conditioned responses, and to react strongly to fear-producing stimuli with his autonomic system. It follows, of course, that differences in environmental pressure could overbalance these innate individual difference patterns; a dysthymic never exposed to pain or fear-producing situations would develop less anxiety than a normal extravert subjected to constant pain and fear-producing situations, as for instance during a prolonged battle. Any final analysis must take into account *both* innate individual differences and environmental happenings; the general formula is probably of the order: Outcome = $f(\text{Predisposition} \times \text{Stress})$.

In a similar manner other symptoms and behaviour traits of individuals at various points of our two-dimensional factor space can be accounted for in terms of the theory here outlined. As this task has been discharged at some length previously (Eysenck, 1957), no effort will be made here to do so again. At various points throughout the book, the reader will find data relevant to the theory; it must be left to his final judgement whether even in the most rough-and-ready fashion our theory does justice to the facts. We will here draw attention to only one further point which is explainable in terms of this general hypothesis. We have drawn attention to the fact that persons high on psychoticism tend to have high scores also on neuroticism, while the reverse is not true of persons having high scores on neuroticism. If we conceive of psychoticism essentially as a disorder of the thought processes (cf. the chapters dealing with cognitive functions and thought disorders), then we might regard it as essentially a powerful *stress* which, when multiplied by an average *predisposition*, produces as the final outcome a strongly emotional and neurotic behaviour pattern. In other words, although the person high on psychoticism is not necessarily high on neuroticism, the strong stress produced by his disordered thought processes results in a high $w \rightarrow K$ sequence leading to strongly emotional reactions. This is, of course, no more than a hypothesis, and supporting evidence is largely lacking; however, the data reviewed in later chapters do give it some empirical support.

It is not to be thought that the general descriptive outline given in this chapter is immutable, or that it is complete. Nothing is more likely than that a much greater number of dimensions will be required to encompass this huge and complex field, and it is by no means unlikely that the final dimensions chosen will not be identical with those here presented. However, reviews are governed by the state of the evidence, not by the possible changes which will take place in a particular field which is being surveyed. At this writing, knowledge is lacking as to what these additional

dimensions of personality might be, how they could be measured, or how they would be related to those described; Cattell's (1957) work indicates possible lines of development, but his work has not dealt with abnormal personality in sufficient detail to make it more than a detailed source of hypotheses. It is interesting to note that, in his latest analysis of the relations obtained between his sixteen personality factors (1957) he discovers second-order factors which bear a striking similarity to neuroticism, extraversion, and psychoticism; such agreement between empirically derived systems of description which were based on quite different samples of the population and quite different samples of objective tests would go a long way towards the validation of the systems in question.

Even more convincing to the writer is the fact that these dimensions which were originally isolated by means of the analysis of interdependence correspond so well to reaction-systems which had been isolated independently, and without thought of individual differences, by physiologists and experimental psychologists. It is not unreasonable to expect individual differences in autonomic reactivity, or in the excitation-inhibition balance, to produce widespread behavioural effects which could not be overlooked in everyday life; it is equally reasonable to expect these effects to be recovered in the form of "factors" in the analysis of questionnaires and objective test reactions. The demonstration that such an analysis of dependence is not only theoretically possible but actually enables us to make testable predictions which empirical research has verified, speaks strongly against the possibility that the descriptive system in question is entirely based on statistical artefact, and has no relation whatever to reality. (Such an integration of the laws of general psychology and the analysis of individual differences appears quite indispensable) if statistical factors are to form part of modern experimental psychology, and not merely an esoteric game for the statistically-minded research worker. (It also appears to be essential if the experimental psychologist is not to continue to disregard what is frequently the major source of variance in the phenomena he is observing—individual differences. Classificatory systems, in normal or in abnormal psychology, must pay equal attention to *general laws* and *reaction types*; they cannot afford the luxury of disregarding one half of the hard-won knowledge of modern empirical psychology).

CHAPTER 2

Abnormalities of Psychomotor Functions¹

AUBREY J. YATES

I. INTRODUCTION

THE term *psychomotor* is defined by Warren (1934) as "pertaining to the motor effects of mental or cerebral processes." Within this general concept, he distinguishes two subtypes of function. Sensorimotor activity involves "responses which follow directly upon sensory stimulation"; whereas ideomotor activity involves "responses which follow upon thought processes, even though of a fleeting character." The term sensorimotor, therefore, pertains to "neural activity, in which both the afferent and efferent segments of the neural arc are involved, or pertaining to the structure contained in such activity." The term ideomotor, on the other hand pertains to "the sequence of movements upon ideas."

This method of conceptualizing certain kinds of behaviour is obsolescent, but it has nevertheless a certain usefulness in bringing together for the purposes of this chapter a large variety of very different tasks. For instance, the classic example of a psychomotor task is the cancellation test, in which the subject is required to cancel certain letters only in a long series. In this situation, the motor act of cancellation follows the perception of the correct stimulus. Now it is clear that a large number of psychological tests can be defined in sensorimotor or ideomotor terms. In the reaction-time (R.T.) test, for instance, which superficially seems very different from a cancellation test, the subject is required to perform a motor act when, and only when, a given stimulus is present. Both of these tests are descriptively similar in that a sensation is followed by a response of a particular kind. On the other hand the best-known example of an ideomotor test is a simple fluency test in which the subject is required to say as many words as possible, beginning, for example, with the letter C.

¹ Previous reviews of psychomotor functions (usually restricted to one or a few aspects of the subject) have been carried out by Hunt (1944), Espenschade (1947), Bayley and Espenschade (1950), Seashore (1951) and Canestrelli (1952). Bills (in Andrews (1948) Ch. 16) discusses methods of studying motor functions and efficiency.

In this case, although there is a general set, there is no specific external stimulus for each separate response—hence the term ideomotor.

It is clear, therefore, from these examples, that psychomotor tests are not in any way concerned as such with motor *ability*. The interest does not lie in the subject's skill in lifting his finger off the key in an R.T. experiment. It is, in fact, implicitly assumed in many psychomotor studies that all subjects are equal in their ability as far as the motor act itself is concerned. Psychomotor tests are simply a means of measuring the *speed* and *accuracy* of central functioning. Interest lies in what goes on *between* the objective onset of the stimulus (e.g. the light in an R.T. experiment) and the objectively observed motor response (e.g. lifting the finger). One major difficulty of course lies in the fact that a number of sequences take place between stimulus and observed response and differences, for example, between subjects in R.T. experiments may be related to differences within one or more of these sequences.¹ Even where records of complex psychomotor responses have been analysed (e.g. Luria, 1932; Davis, 1948), it has been assumed that these responses do not indicate impairment of the motor system itself (such as might follow injury to the motor cortex) but rather some kind of central disorganization which is *reflected* in the motor response.

It is clear that there will be a boundary where the change from a motor response which is used to reflect individual differences in speed and accuracy of central functions to a motor response which can be said to involve individual differences in the skill required to make the response itself will be difficult to detect. For example, it would be easy to analyse finger or manual dexterity in a way similar to that outlined above, i.e. as a constant interchange of stimulus-response mechanisms.

¹ This problem, of course, is a very old one. It was, for instance, the subject of much research by Wundt (1873-4), following upon the original experiments of Donders (1865).

Hence the tests included in this chapter are somewhat arbitrary. After an examination of various possibilities it was decided to divide the tests into sections according to the type of response required. Three levels were found necessary to satisfy this criterion, the tests being allocated as follows—

A. Simple motor response mechanisms

1. Simple and complex R.T.
2. Cancellation
3. Tapping
4. Davis-type tests

B. Complex motor response mechanisms

1. Luria-type test
2. Mirror-drawing
3. Manual and finger dexterity
4. Rail-walking

C. Continuous Motor response tasks

1. Static ataxia
2. Body sway (suggestibility)
3. Steadiness
4. Perseveration
5. Fluency
6. Persistence
7. Continuous work

The present chapter will be organized into two sections, one attempting to summarize the facts concerning psychomotor functions, in so far as these have been clearly demonstrated, the other attempting to relate these facts in an orderly way and evaluate the various theories which have been put forward to account for the facts. Before this can be done, however, some of the general difficulties met with in the analysis will be briefly mentioned. These problems should be borne in mind when reading the chapter.

One of the major problems which has occupied workers in this field has been the puzzling question of the specificity or generality of the ability required to perform psychomotor tasks. The earlier studies in the field (e.g. Seashore, 1928, 1930) suggested that the ability to do one type of motor task was relatively independent of the ability to do any other. Many functional analyses have since been carried out¹ and the results are quite clear. For example, the analysis of thirty-eight psychomotor tests by Fleishman (1954) resulted in a matrix of almost uniformly positive, but largely low correlations.² Consequently although the

existence of a general factor of psychomotor ability cannot be doubted, its importance has been generally rejected and a solution resulting in independent group factors preferred. Thus, Fleishman analysed his correlation matrix into ten independent group factors (Table II.1). The most interesting feature of this

TABLE II.1
SOME PSYCHOMOTOR FACTORS IDENTIFIED
BY FACTOR ANALYSIS

(Adopted from E. A. Fleishman, "J. Exp. Psychol.," 48, 437-454, 1954)

- I. Wrist-finger speed
- II. Finger dexterity
- III. Rate of arm movement
- IV. Aiming
- V. Arm-hand steadiness
- VI. Reaction-time
- VII. Manual dexterity
- VIII. Psychomotor speed
- IX. Psychomotor co-ordination
- X. Spatial relations

table lies in the narrow abilities which are defined by each of the factors. The wrist-finger factor, for instance, is defined primarily by two simple tapping tests. The R.T. factor, on the other hand, is defined by visual and auditory R.T. only. The intercorrelation of these four tests (Table II.2) shows clearly that proficiency in R.T. bears little relationship to proficiency in tapping—a surprising finding in view of the apparent simplicity of the two tasks which appear to be measures of uncomplicated motor speed. Yet this finding has been repeated many times.

TABLE II.2
INTERCORRELATIONS OF FOUR
PSYCHOMOTOR TESTS

(From E. A. Fleishman, "J. Exp. Psychol.," 48, 437-454, 1954)

	2	3	4
1. Visual R.T.	0.56	0.30	0.24
2. Auditory R.T.		0.20	0.17
3. Medium tapping			0.72
4. Large tapping			---

The factors isolated by Fleishman should not be regarded as definitive. The factors obtained by such analyses are dependent on the nature of the tests used, which have differed widely from study to study. Thus, Seashore, *et al.* (1940) factor-analysed a group of 21 tests and isolated five factors which they designated—

1. Speed of single reaction.

2. Finger, hand and forearm speed in restricted oscillatory movement.

¹ Excellent reviews of these studies will be found in Seashore (1940, 1951), Fleishman (1953) and others.

² Calculations made by the author on available studies, e.g. Fleishman (1954), Rimoldi (1951), suggest that the first factor in an unrotated solution usually accounts for about 25 per cent of the total variance, a figure at least as high as that found for personality factors such as neuroticism.

3. Forearm and hand speed in oscillatory movements of moderate extent.

4. Steadiness or precision.

5. Skill in manipulating spatial relations.

The first factor was defined by four R.T. tests, horizontal tapping and rotation of speed drill, in contrast with Fleishman who found tapping and R.T. to be quite different abilities.

The majority of factorial studies carried out have little direct bearing on this chapter, since in most instances they were carried out on highly selected groups for special purposes¹ (for this reason also the group factors have been stressed more than the general factor). However, it is a fact that few investigations into psychomotor function in abnormal subjects have made any use of factorial methods or even of those results from factorial studies which are of general importance. One immediate difficulty, of course, would seem to lie in the very use of psychomotor tests in abnormals. If the correlations between tests are on the whole much lower than those found with intelligence tests then it would seem to be difficult to put forward any general theory to account for differences in psychomotor performance in abnormals as compared with normals; since poor performance on one test might be accompanied by good performance on another, if the correlation is low.

This leads to the second major problem. While intercorrelations between psychomotor tests tend to be low, though positive in normal groups, in abnormal groups the correlations tend to be very much higher, i.e. an abnormal who is poor on one test will tend to be poor on all other psychomotor tests. This difference can be seen clearly in data provided by Shapiro and Nelson (1955), whose figures are summarized in Table II.3.² The explanation of this curious and important fact has usually been given in terms of the small spread of scores shown by normal subjects, i.e. it is argued that the tests are much easier for normals than for abnormals. That this is not the correct explanation is shown quite clearly by the data provided by Fleishman (1954) in the study already referred to. He gives means and S.D.s for his normal group of subjects for all thirty-eight tests; on nearly all of these tests the distribution of scores is quite satisfactory for the purposes of correlation.³ Furthermore, the reliability of Fleishman's tests is quite satisfactory, most of them being above 0.70. Although,

therefore, it is true that abnormal groups usually show a wider range of scores than do normal groups, the differences would not appear to be such as to account for the difference in correlations between the tests.

TABLE II.3
NUMBER OF SIGNIFICANT CORRELATIONS
BETWEEN ERROR-FREE SPEED TESTS

(Total number of correlations in each sample = 45)

(From M. B. Shapiro and E. Nelson, "Brit. J. Med. Psychol.,"
28, 239-256, 1955)

Sample	5 per cent level r = 0.44 to 0.55	1 per cent level r = 0.56
Normals . . .	3	1
Schizophrenics . . .	8	19
Manic-depressives . . .	3	22
Organics . . .	8	12
Neurotics . . .	9	13

A further problem consists of the scattered and uncoordinated nature of many of the studies published on psychomotor functions in abnormals. The use of different kinds of tests to measure the same attribute (e.g. reaction-time), the use of criterion groups of abnormal subjects chosen in quite different ways (though bearing the same title) and the purely empirical nature of much of the research has led to results both confusing and discouraging. For this reason, stress has been laid in this chapter on those studies which have been most carefully performed and whose results are relatively unequivocal. In most cases, early and perhaps pioneering studies are neglected in favour of later, better controlled studies.¹ In view of the known unreliability of diagnosis, reference in general will be made only to differences between neurotics (and within neurotics, between dysthymics and hysterics), psychotics and normals.

A much neglected problem is that of the role of learning in psychomotor tests. In general, it has been assumed that practice or learning has little or no effect on performance, since the tasks involved (e.g. simple R.T., tapping, cancellation, etc.) are so simple that the subject works at his maximum right from the start. That this is not the case has most clearly been demonstrated quite recently by King (1954). Fig. 2.1 shows the improvement in score on three simple tapping and dexterity tests for schizophrenics and normals over a period of several trials. It is clear that there is a learning curve for even such a simple task.

¹ Most of the more sophisticated studies have been carried out in an attempt to devise tests for the selection of recruits for highly skilled posts in the American armed forces.

² These were a number of simple motor speed tests of the Babcock series on which no errors were made by the patients tested by Shapiro and Nelson.

³ The argument concerning the distribution of "normal" scores has usually been put forward in those studies of a clinical nature where the numbers involved have been small.

¹ At the beginning of each section, reference will be made to recent reviews of the literature, where these exist.

In so far as differences in learning are known to exist they will not be treated in this chapter;¹ it should be remembered, however, that differences in learning may account for some of the puzzling findings with

amount of learning. On the other hand, he includes a number of tasks (e.g. simple R.T., tapping) where the learning involved must be *relatively* small. Yet he calls all of these tests psychomotor tests. Fortunately,

FIG. 2.1 (a). LEARNING CURVES ON THE TAPPING TEST FOR THE CHRONIC AND NORMAL GROUPS
Each point plotted represents the mean of five trials.

FIG. 2.1 (b). LEARNING CURVES ON THE DEXTERITY TESTS FOR THE CHRONIC AND NORMAL GROUPS
Each point plotted represents one trial.
(From King, 1954)

abnormal groups. This leads naturally to the problem of the relationship between skilled and unskilled motor tasks. Fleishman (1954), for instance, uses many tests which undoubtedly could be termed skilled tasks, i.e. tasks which involve a very considerable

the problem is solved by the fact that very few tests involving *motor skills* have been given to abnormal groups. These include manual and finger dexterity and mirror-drawing, which will be included in this chapter. The choice of measures to be discussed is, however, somewhat arbitrary.

¹ See Chapter 13 by G. Jones.

II. PSYCHOMOTOR FUNCTION OF NORMALS AND ABNORMALS

Simple Motor Response Mechanisms

REACTION-TIME (R.T.)¹

The R.T. experiment has perhaps been more frequently used in the study of psychomotor function in abnormal subjects than any of the other tests we shall study; also a vast array of information is available for comparative studies on normal subjects.

The early experiments on abnormal subjects (e.g. Saunders and Isaacs, 1929; Wells and Kelley, 1922; Scripture, 1916; Bevan-Lewis, 1892) were of the most simple kind, involving the measurement of simple reaction-time to an auditory or visual stimulus and were carried out on miscellaneous, small groups of psychiatric patients. Later work (especially that of Huston and Senf, 1952; Huston and Singer, 1945; Rodnick and Shakow, 1940; Knehr, 1954; King, 1954; and Tizard and Venables, 1956) has been more concerned to test the validity of certain theories concerning responsiveness in abnormal (usually schizophrenic) patients.

The methodology adopted by the different investigators has been very variable. Some of the factors which have been controlled include—

- (i) Simple R.T. versus complex R.T.
- (ii) Short interval versus long interval between stimuli.
- (iii) Regular interval versus irregular interval between stimuli.
- (iv) Warning signal versus no warning signal.
- (v) Auditory versus visual stimulus.
- (vi) Auditory versus visual warning signal.
- (vii) Type of response required—
 - (a) simple lift R.T.;
 - (b) simple jump R.T.;
 - (c) simple disjunctive lift R.T.;
 - (d) simple disjunctive jump R.T.;
 - (e) reaction by pressing;
 - (f) reaction by lifting and pressing in own time;
 - (g) movement in own time from one key to another.
- (viii) Musculature involved—
 - (a) hand—left or right;
 - (b) foot—left or right;
 - (c) other limbs.
- (ix) Groups used. These include—
 - (a) normals;
 - (b) schizophrenics (acute and chronic);

- (c) manic-depressives (in manic or depressed state);
- (d) organics;
- (e) neurotics;
- (f) pseudoneurotic schizophrenics.

Broadly speaking, however, the technique developed by Shakow and his colleagues is that now used by most investigators—principally with the aim of testing the hypothesis set up by Shakow. His technique was as follows. The stimulus to which the response was required (usually a sound, but sometimes a light) would be presented at regular or irregular intervals after a warning sound. When the regular interval was used, there would be ten trials for each interval of 1, 2, 4, 7.5, 15 and 25 seconds, each set of trials for a given interval being completed before the next interval was started. There was a 5-second interval between each trial and a rest of one minute after each series of ten trials. In effect, the subject knew how soon after the warning bell, the stimulus would appear. In the irregular method, however, the interval between the warning bell and the stimulus was varied at random (but in such a way that each interval was presented an equal number of times) so that the subject did not know whether the stimulus would follow the warning after one second or after 7.5 seconds or after 25 seconds, etc. In this part each of the intervals was presented a total of twelve times in random order and there was a rest pause of 3 minutes after thirty-six trials.

This technique has been used on a number of occasions, both with and without drugs, and with normal and abnormal subjects. Practically all investigators use simple R.T. to sound or light, presumably because choice R.T. is considered too difficult for many patients.¹

Other investigators (e.g. Hall and Stride, 1954; King, 1954), have used simple R.T. with a standard interval (5 seconds) with no warning, or delayed R.T. with a long interval (10 seconds) but with warning. A few investigators (Hall and Stride, 1954; King, 1954) have investigated the practice effect of repeated trials on R.T. It is obvious that the number of different ways of investigating R.T. in abnormals is legion.

The results obtained by these methods present a rather confused picture, but the following results would seem to be relatively clear-cut—

- (i) Undifferentiated schizophrenic groups are significantly slower than depressives and neurotics (Hall and Stride, 1954); normals (Huston *et al.*, 1937; Huston and Singer, 1945; Rodnick and

¹ Various aspects of R.T. and factors which influence it have been reviewed by Michon (1939), Chochole (1948), Teichner (1954) and Woodworth and Schlosberg (1954). The work of Shakow and his colleagues has been brought together in Shakow (1946).

¹ But cf. Pascal and Swensen (1952).

Shakow, 1940; Tizard and Venables, 1956); and defectives (Tizard and Venables, 1956).

(ii) Chronic schizophrenics are significantly slower than acute schizophrenics, depressives and neurotics (Huston and Senf, 1952) and normals (King, 1954). Chronic psychotics are poorer than acute psychotics on a complex R.T. test (Windle and Hamwi, 1953; King, 1954).

(iii) Acute schizophrenics are *not* significantly slower than depressives, but are significantly slower than neurotics (Huston and Senf, 1952).

(iv) Neurotics are significantly faster than depressives (Hall and Stride, 1954; Huston and Senf, 1952), chronic and acute schizophrenics (Huston and Senf, 1952), and are not significantly slower than normals matched for age (King, 1954; Hall and Stride, 1954).

(v) Depressives are not significantly different from normals if the groups are roughly matched for age (Hall and Stride, 1954).¹

These results are not very clear-cut. It is not easy to divide the various groups into psychotic and neurotic, since both Hall and Stride, and Huston and Senf employed psychotic depressives who apparently behave quite differently from schizophrenics, while the latter can be split into acute and chronic. Again the results with regard to neurotics are equivocal, but the differences which exist would seem to be much less than for groups of psychotics. The one clear-cut result would seem to be that patients diagnosed as chronic schizophrenics have consistently been found to be significantly slower than all other psychiatric groups, and than normals.²

Sex differences assumed some importance in the study by Hall and Stride, but were found to be minimal in most other studies, especially the large-scale one of King. With regard to age differences, Hall and Stride found that in the neurotic and depressive groups, subjects under 40 tended to be significantly faster than subjects over 40, while King found that subjects showed significant slowing with age but that old schizophrenics tended to be faster than young ones.

Research, however, has not been confined to the investigation of group differences only. Certain other aspects of R.T. have been investigated, with the following main results—

(i) Schizophrenics show more inter- and intra-individual variability in their R.T. responses than do normals (Huston *et al.*, 1937; Huston and Senf,

1952; Huston and Singer, 1945; King, 1954; Knehr, 1954; Rodnick and Shakow, 1940; Tizard and Venables, 1956) and this increased variability is apparent both under normal testing conditions and under the influence of drugs.

(ii) When the regular procedure is compared with the irregular procedure, schizophrenic patients show a curious reversal of behaviour. For short intervals of time the irregular procedure leads to a longer R.T. than does the regular procedure (for the same intervals). With longer intervals, the pattern is reversed, the change in behaviour appar-

TABLE II.4

CHANGE IN R.T. UNDER VARYING PREPARATORY INTERVALS FOR REGULAR AND IRREGULAR PROCEDURE IN NORMALS AND SCHIZOPHRENICS

(From E. H. Rodnick and D. Shakow, "Amer. J. Psychiat.", 97, 214-225, 1940)

Interval (seconds)	Regular procedure mean	Irregular procedure mean
A. 25 SCHIZOPHRENICS		
	Milliseconds	Milliseconds
1	668.7	722.5
2	544.4	665.6
4	531.0	619.5
7.5	648.5	583.0
15	639.3	587.9
25	653.5	560.8
B. 10 NORMAL CONTROLS		
1	262.7	315.2
2	239.2	290.7
4	261.1	296.6
7.5	275.5	303.6
15	278.1	296.0
25	312.3	305.3

ently taking place somewhere between the intervals of 4 seconds and 7.5 seconds. The validity of this finding seems undoubted (Rodnick and Shakow, 1940; Tizard and Venables, 1956).¹ In Rodnick and Shakow's data there is some suggestion that

¹ These results refer to studies using R.T. to sound or light; Huston (1935) found no differences between schizophrenics and normals on patellar tendon reflex.

² The negative results of Wells and Kelley (1922) and Saunders and Isaacs (1929) cannot be taken too seriously because of the small numbers involved.

¹ The negative findings of Knehr (1954) can be disregarded on a number of grounds, the principal objection to his study being that he used only two intervals (2 seconds and 10 seconds). This meant, of course, that the "irregular" presentations were such in name only; since the patient would soon realize that if the irregular interval were not 2 seconds, it could only be 10 seconds, whereas in Rodnick and Shakow's study, it might be 4, 7.5, 15, or 25 seconds. For other criticisms of Knehr's study, see Tizard and Venables (1956).

the same phenomenon may occur *later* (in terms of intervals) in normals.¹ The figures are shown in Table II.4.

Huston and Senf (1952) found that the Set Index was not significantly affected by the degree of co-operation, duration of illness and change of affect with drugs. These findings do not agree with those of King (1954). Although he found no relationship between R.T. and *duration* of illness, he did find a clear relationship between R.T. and *severity* of illness.

CANCELLATION

The cancellation test is a classic example of a psychomotor task. It is clearly analogous to a choice R.T. test in that the subject has to adopt a set and respond to the correct stimulus when it appears at irregular intervals by making a simple motor response. Although this test was extensively used by earlier workers in its many different forms² surprisingly little systematic use has been made of it in abnormal psychology. Mohr and Gundlach (1927) found no differences between asthenics and pyknics when intelligence was partialled out, a finding confirmed by Klineberg, Asch and Block (1934). More recently, Bonnet (1953) investigated changes in speed and accuracy on a cancellation test in psychotic patients who were given five to twenty repetitions of the test over a period of eight months.

TAPPING

Even such a simple test as tapping may be administered in a number of forms. Some investigators, for instance, have been interested in the simple speed of tapping on a single plate; others have studied oscillatory tapping alternately on two plates; others, again, have measured the spread or scatter of the taps. Again, preferred speed has been studied in contrast with maximum speed; while ability to repeat or copy a certain rhythm has been investigated.

Even with such a simple function, the results obtained on abnormal subjects are inconsistent—

(i) It is largely agreed that *speed* or *rate* of tapping does not discriminate between normals and neurotics (H. J. Eysenck, 1952a; S. B. G. Eysenck, 1955; Wulfeck, 1941; Himmelweit and Petrie, 1951). King (1954) found that his neurotics were significantly slower than his normals, but his neurotic group was small ($N = 23$) and the mean difference very small.

(ii) While H. J. Eysenck (1952a) found that two

measures of *scatter* discriminated significantly between normals and neurotics on the one hand (neurotics showing more scatter) and between dysthymics and hysterics on the other (dysthymics showing more scatter), these results were not repeated by S. B. G. Eysenck (1955) who found no difference in scatter between normals and neurotics.

(iii) Shakow and Huston (1936) found that psychotics were significantly *slower* in tapping rate than normals (with schizophrenics slower than manic-depressives within the psychotic group). This finding was confirmed by King (1954) for *chronic* schizophrenics who were slower than both normals and neurotics. S. B. G. Eysenck (1955) found that while individual left- or right-hand speed scores did not differentiate between normals, neurotics and psychotics, the latter were slower than either of the other two groups on a combined score. The only contrary evidence here is that of Wulfeck (1941) who found no differences between normals, schizophrenics, depressives and neurotics.

(iv) S. B. G. Eysenck (1955) found that psychotics did not differ in amount of scatter from normals or neurotics.

We may conclude that *rate* of tapping does not discriminate between normals and neurotics but that there is a suggestion that scatter may do so. On the other hand, rate of tapping does discriminate between psychotic and other abnormal or normal groups, whereas scatter does not.¹

CONTROL MOVEMENTS (DAVIS)

Davis (1946a, 1946b, 1947, 1948, 1949a, 1949b) carried out a series of experiments on the causes of pilot error. In some experiments he used a simulated cockpit in which instruments on a panel respond realistically to movements of the controls; in other experiments, he used an apparatus in which a pointer could be moved to a given position to the right or left of it.

He observed two types of errors; errors of *over-action* and errors of *inertia*. Subjects who were over-active "obtained large scores on control movements . . . responses to instrument deviations were excessive, the extent and gradient of the movements being greatly increased and over-correcting frequent. Numerous restless movements were observed . . . subjects felt excited and under strain, tense and irritable and sometimes frankly anxious." Subjects who were inert, on the other hand, made "errors which were large and of long duration, whereas

¹ A puzzling feature of Rodnick and Shakow's data is the consistently faster R.T. for longer preparatory intervals under the irregular procedure in the schizophrenic group.

² Whipple (1924) gives a summary of the different kinds of cancellation tests and the problems involved in measurement.

¹ Penrose and Wilson (1942) describe a peculiar spatial distribution of responses which they claim are found in psychotic patients when asked to tap on the table with a stylus. Various examples are given but no methods of measurement are described, nor any statistical results.

activity, represented by scores of control movements, was relatively little. . . . The individual responses were less hurried and less disturbed by restless movements than were those of the pilots showing the overactivity reaction, but they were often more extensive than at the beginning of the test. . . . Subjects reported that their interest had flagged and that their concentration had failed. A feeling of strain had now given way to one of mild boredom, tedium or tiredness."

Davis (1948) went on to show that if responses in the test are classified into three categories (normal, overactive, inert), then only 33 per cent of neurotic pilots showed a normal reaction, compared with 75 per cent of normals. Further, pilots suffering from anxiety states showed a strong tendency to make overactive responses; whereas pilots suffering from hysteria tended to display inert responses. (Table II.5.)

TABLE II.5
TEST RESULTS OF NORMAL AND NEUROTIC PILOTS

(From D. R. Davis, "Pilot Error. Some Laboratory Experiments" (H.M.S.O., 1948))

	Normal		Overactive		Inert		Total N
	N	Per centage	N	Per centage	N	Per centage	
Normal pilots	268	75	59	17	28	8	355
Neurotic pilots	13	33	11	28	15	38	39
Acute anxiety state	6	43	7	20	1	7	14
Hysteria	1	12.5	1	12.5	6	75	8
Other	6	35	3	18	8	47	17

In another experiment (Davis, 1946b) 355 fit pilots were classified by two psychiatrists with regard to predisposition to neurosis as: nil, slight, moderate; and further classified on the Cockpit test as normal, over-

TABLE II.6
ASSOCIATION OF NEUROTICISM AND TEST SCORE

(From D. R. Davis, "J. Neurol. Psychiat.", 9, 119-124, 1946b)

Predisposition	Type of response			
	Normal	Over-active	Inert	Per cent normal
Nil	130	13	12	84
Slight	113	32	9	73
Moderate	25	14	7	54
Per cent moderate	9	24	25	

active, inert. The results (Table II.6) indicate a significant association between grade of predisposition and test class, the percentage of normal responses decreasing with increasing predisposition to neurosis. Fit pilots who were rated as obsessional tended to fall into the overactive class.

In an experiment (Davis, 1949a) using a simple pointer apparatus instead of the Cockpit, healthy, acutely anxious and hysteric pilots were given "extent" scores (ranging from 3-8) on the test. The results (Table II.7) showed clearly that the acutely anxious pilots tended to make more extensive responses than did normals; the hysterics showing the opposite tendency. Further, the response time of the hysterics was significantly *longer* than that of the normals, the latter being similar in this respect to the acutely anxious.

TABLE II.7
DEGREE OF ERROR OF NORMAL, ANXIOUS AND HYSTERIC PILOTS

(From D. R. Davis, "Quart. J. Exp. Psychol.", 1, 22-28, 1949a)

	Distribution of cases (Extent scores in arbitrary unit)						
	3	4	5	6	7	8	Total
Healthy pilots	1	3	21	29	14	1	69
Acutely anxious	1	1	2	3	6	2	15
Hysterics	4	5	2	1	0	0	12

Davis's experiments may be summarized in the following way—

1. Neurotics tend to make more errors of judgement compared with normals.
2. Within the neurotic group, dysthymics tend to make errors of overactivity, hysterics errors of inertia.
3. Similar tendencies are found within normal groups.

Davis (1946) also noted that "the errors in the instrument readings increased in size towards the end of the test . . . and there were few large errors in place of many small ones." Similarly, the number of errors in resetting the "fuel contents" indicator fell from the first to the third period but then increased significantly. These phenomena, which Davis called "late effects" indicate that, in general, errors of inertia tend to predominate over errors of overactivity in *all subjects* provided the test is continued for a long enough period.

Complex Motor Response Mechanisms

THE LURIA TECHNIQUE¹

This technique is a development by Luria (1932) of the original work of Nunberg (1918) who combined the Word Association test with measurements of hand movement at the time of and between verbal responses. The underlying rationale is that the internal conflict thought to occur when the subject is required to respond to an emotionally disturbing stimulus² will be reflected in motor movements which, being overt, can be recorded. Many studies have been published which support this general hypothesis.³ A large number of variables have been recorded which may be classified generally as follows—

1. Reaction-time measures—
 - (a) time of verbal response;
 - (b) time of manual response (Speer, 1937; Eysenck, S. B. G., 1955);
 - (c) variability of time of response.
2. R-hand response (usually voluntary, made at time of verbal response)—
 - (a) regularity and duration of response (Malmo *et al.*, 1951);
 - (b) height (Speer, 1937);
 - (c) number of disturbances (Speer, 1937).
 - (d) number of double depressions;
 - (e) number of depressions omitted;
 - (f) three longest—three shortest responses. } (Eysenck, S. B. G., 1955)
3. L-hand response (usually involuntary, both at time of R-hand response and between R-hand responses)—
 - (a) height, length, number of changes in direction, number of items producing L-hand response (Speer, 1937);
 - (b) number of reversals;
 - (c) maximum distance from base line. } (Eysenck, S. B. G., 1955)
4. Length of base line, i.e. actual length of the kymographic record (Eysenck, S. B. G., 1955).

Little attention has been paid to the degree of relationship between these variables. Malmo *et al.* (1951), Albino (1948), Krause (1937) and Sharp (1938) give figures which indicate low positive correlations between L- and R-hand disturbance, but indicate no

relationship between amount of motor disturbance and speed of response (R.T.). Clarke (1950) showed that it was important to partial out differences in intelligence between psychiatric groups before group differences could be examined.

The results obtained on psychiatric groups may be summarized as follows—

(i) R-hand voluntary response is significantly more disturbed in neurotics than in normals (Clarke, 1950; Malmo *et al.*, 1951; Eysenck, S. B. G., 1955).

(ii) L-hand involuntary response is significantly more disturbed in neurotics than in normals, provided the apparatus used is sufficiently sensitive (Albino, 1948; Clarke, 1950; Malmo *et al.*, 1951; Eysenck, S. B. G., 1955).

(iii) Both local and general motor disturbance is greater in neurotics than in normals (Barnacle *et al.*, 1935; Ebaugh, 1936).

These conclusions are further supported by the work of Morgan and Ojeman (1942) who found significant differences between groups rated as having low, intermediate and high degrees of conflict.

(iv) There is some evidence that the motor disorganization shown by dysthymics is different from that shown by hysterics (Barnacle *et al.*, 1935; Malmo *et al.*, 1951). Speer (1937) related introversion-extraversion to amount of L-hand disturbance and concluded that introverts tended to respond more than extraverts with the L-hand (i.e. showed more involuntary disturbance). Ebaugh's (1936) study indicated that anxiety cases showed more *general* disturbance than hysterics; and possibly more *local* disturbance.¹

(v) Results obtained with psychotics indicate that they show at least as much disorganization as neurotics (Malmo *et al.*, 1951), if not more (Eysenck, S. B. G., 1955).² Shuey (1937) distinguished four types of motor reaction with the R-hand (small, large, mixed, chaotic) and attempted to relate these to specific psychotic groups (manic-depressive, paranoid, catatonic) without much success.

The above general findings have been confirmed by the recent well-controlled study of S. B. G. Eysenck (1955). Using one hundred and twenty-three controls, fifty-five psychotics and fifty-five neurotics and a number of response categories, she obtained the results shown in Table II.8. From these data she concluded that R-hand disturbance differentiates better

¹ There is no adequate published summary of work on this test since the publication of Luria's (1932) book; unpublished reports may be found in Eysenck, S. B. G. (1955) and Clarke (1950).

² Clarke (1950) also used an electric shock as a stimulus.

³ Olson and Jones (1931); Huston *et al.* (1934); Burt (1936); Runkel (1936); Brandt (1937); Gardner (1937); Krause (1937); Reymert and Speer (1939); Morgan and Ojeman (1942).

¹ Ebaugh's results are difficult to interpret since he provides no measures of dispersion.

² Malmo *et al.* (1951) considered disorganization was primarily a function of severity of illness.

than L-hand disturbance, and that psychotics show even greater disorganization than do neurotics.

TABLE II.8

DIFFERENCES BETWEEN NORMALS, NEUROTICS AND PSYCHOTICS ON THE LURIA TEST

(From S. B. G. Eysenck, *Ph D. Thesis*, 1955)

Variables	Controls (N = 123)	Neurotics (N = 55)	Psychotics (N = 55)	F	p
	M	M	M		
1. <i>Motor R.T.</i>					
No. of delays	22.7	27.0	29.1	16.61	0.001
Σ total delays	112.2	233.3	294.5	20.13	0.001
2. <i>R-hand disturbances</i>					
No. double depressions	2.0	4.7	5.9	11.71	0.001
No. omitted depressions	0.1	0.3	1.8	9.79	0.001
Σ 3 longest — Σ 3 shortest R.T.	14.2	16.7	18.6	5.21	0.01
3. <i>L-hand disturbances</i>					
No. reversals	8.2	8.4	13.5	4.18	0.01
Max. distance from base line	1.5	1.9	2.2	3.69	0.05
4. <i>Length of baseline</i>	297.9	406.9	503.2	21.74	0.001

MIRROR DRAWING¹

Results obtained on the mirror-drawing test which has been extensively used with normal and abnormal groups are not so clear-cut as those obtained on the Luria test. Earlier studies suggested that speed and error scores in this test discriminate between "stable" and "unstable" individuals (Ball, 1929; Brower, 1948); that there is a negative correlation between mirror-drawing ability and inadequacy of social adjustment (Louttit, 1943); that psychotics and delinquents are significantly slower than normals (Peters, 1946); and that anxiety cases are significantly slower than normals (Wechsler and Hartogs, 1945).

Two carefully controlled studies throw light on these suggestions (in both cases a diamond-shaped figure was used compared with the more common star-shape). Using the groups of normals, neurotics and psychotics already referred to, S. B. G. Eysenck (1955) found that psychotics were significantly poorer than either neurotics or normals on five speed measures (first time, longest time, shortest time, average time, and first minus third time). The neurotics were also slower than the normals, but the main differences were much smaller.² These results are in agreement with those of Eysenck (1952a) who found

¹ Early studies are reviewed in Whipple (1924); later studies in Brower (1948); Clarke (1950); Waters and Sheppard (1952); and Eysenck, S. B. G. (1955).

² Average time for controls was 44.27 seconds; for neurotics 62.60; for psychotics 98.00 ($p < 0.001$). Clarke (1950) found no difference between normals and neurotics or between hysterics and dysthymics with respect to time scores.

highly significant differences on time taken between normals and psychotics.

We may conclude that the mirror-drawing test discriminates at a high level between normals and psychotics and possibly between normals and neurotics. No reliable information is available concerning errors.

MANUAL AND FINGER DEXTERITY

Relatively little work on abnormal subjects has been reported with this type of test. Lubin (1951) found a correlation with the normal-neurotic dichotomy of about +0.60, while O'Connor (1951), testing high grade mental defectives obtained a neurotic factor saturation of 0.43 on manual and finger dexterity tests.

S. B. G. Eysenck (1955) found that parts M, N, O and P of the USES battery all discriminated significantly between psychotics and normals, while neurotics fell in between, but were significantly poorer than normals. These results support those by Eysenck (1952a) who compared normals with neurotics, the neurotics being significantly poorer on all four parts of the test. A comparison of the two studies is shown in Table II.9.¹ Tizard and O'Connor (1951) also found that manual and finger dexterity tests had significant loadings on a factor of neuroticism.

TABLE II.9

A COMPARISON OF TWO STUDIES ON MANUAL AND FINGER DEXTERITY TESTS

(From H. J. Eysenck, "Scientific Study of Personality," 1952, and S. B. G. Eysenck, *Ph D. Thesis*, 1955)

	S. B. G. Eysenck, (1955)		Eysenck (1952)	
	Controls	Neurotics	Controls	Neurotics
	M	M	M	M
Part M	75.45	72.62	77.29	71.87
Part N	88.60	86.75	83.06	75.58
Part O	27.76	25.29	26.22	23.60
Part P	25.65	23.95	25.56	22.90
Total	217.36	208.61	212.13	193.95

Petrie (1948) found that dysthymics were significantly better than hysterics in the O'Connor Tweezers Test.

RAIL-WALKING TEST

This test, which was devised by Heath (1942, 1943, 1944, 1946, 1949) usually employs two 9 ft long rails,

¹ The results are remarkably consistent. The scores obtained by Eysenck (1952a) are slightly lower all round, presumably because the amount of pre-test practice was curtailed by him.

one 4 in. and one 2 in. wide, and one 6 ft long rail, 1 in wide. The test is given in an untimed form, the subject being required to walk along it in his stockinged feet (Heath, 1942). It has been extensively standardized (Heath, 1942, 1944, 1949) and has a high reliability.

Heath (1946) discovered an adjustment syndrome, characterized by poor motor co-ordination among other things, and the possible relationship of this lack of motor co-ordination to neuroticism was confirmed by the work of Tizard *et al.* (1950) and Tizard and O'Connor (1951). Using it along with a number of other tests, they found that it had a significant loading on the neuroticism factor which resulted from their factorial analysis. Unfortunately little work has since been carried out with this test on psychiatric groups.

Continuous Motor Response Tests

STATIC ATAXIA¹

In this test the subject is told simply to stand still and relax, with the eyes closed and the hands hanging down the side, feet together. The test lasts for 30 seconds, usually, and maximum sway either forward or backward is the score. Data for one hundred and twenty normal controls and 1,230 neurotics (Eysenck, 1952a) show that 81 per cent of normals swayed less than 1 in., compared with only 32 per cent of neurotics; no normals swayed more than 2 in., while 31 per cent of neurotics did so. In another study (Eysenck, 1944), four times as many neurotics swayed more than 1 in. when compared with normals.

BODY SWAY (SUGGESTIBILITY)²

Two main problems have confronted workers on suggestibility. The first of these concerns the question whether or not suggestibility tests have anything in common (i.e. define one or more factors). The second concerns the relationship between suggestibility and abnormality.

(a) Types of Suggestibility

Early investigations produced conflicting reports. Thus Aveling and Hargreaves (1921) and others believed they had demonstrated the existence of general and group factors of suggestibility whereas Estabrooks (1929) reported zero or very low correlations. Still other writers believed in the existence of group factors of suggestibility—Hull (1933), for example, distinguished “prestige” and “non-prestige” suggestion.

A considerable amount of light was thrown on this

problem by the researches of Eysenck. In one study, for example (Eysenck, 1943) he used eight tests of suggestibility and intercorrelated the resultant scores, with results shown in Table II.10. Two clear-cut independent factors emerged.¹

TABLE II.10
FACTOR ANALYSIS OF 8 TESTS OF
SUGGESTIBILITY

(From H. J. Eysenck, “*J. Neurol. Psychiat.*” 6, 22–31, 1943)

Test	Loadings	
	Factor I	Factor II
1. Weights (personal) . . .	+ 0.509	– 0.371
2. Lines (personal) . . .	+ 0.772	– 0.002
3. Weights (impersonal) . . .	+ 0.558	+ 0.048
4. Lines (impersonal) . . .	+ 0.386	+ 0.016
5. Pendulum . . .	+ 0.094	+ 0.386
6. Body sway . . .	– 0.041	+ 0.623
7. Levitation up . . .	– 0.194	+ 0.370
8. Levitation down . . .	– 0.100	+ 0.546

(i) *Primary Suggestibility*: This factor is revealed by tests of the ideomotor type, i.e. psychomotor tests in which a motor movement is executed by the subject following the repeated suggestion by the experimenter that such a movement will take place, without conscious participation in the movement on the subject's part. The test which most satisfactorily defines this factor is Hull's Body Sway Test which has been extensively used for this purpose. The factor is also defined by the Chevreul Pendulum Test, the Arm Levitation Test and the Press-Release Test.²

(ii) *Secondary Suggestibility*: This factor is defined by tests other than motor tests and need not be considered further.³

The main characteristics of primary suggestibility are as follows (Eysenck, 1943)—

1. It is distributed in the experimental population as a U-curve (this U-curve being, however, an artefact of the method of measurement (Eysenck and Furneaux, 1945)).
2. It correlates in a significantly non-linear way with intelligence (subjects of average I.Q. being most suggestible).
3. It may manifest itself in a positive or negative response.
4. It is a highly reliable phenomenon.

¹ The results were repeated in a subsequent, more extensive study (Eysenck and Furneaux, 1945).

² See Eysenck (*Dimensions of Personality*, p. 166, 1947) for a description of these tests.

³ Eysenck (1947) thinks there is some evidence for a third factor of suggestibility (prestige).

¹ Edwards (1942) has reviewed the literature prior to 1942, and the factors which must be controlled in any study of static ataxia (Edwards 1942, 1946a, 1947). See also Travis (1945) and Eysenck (1947, Appendix B).

² For reviews of the literature, see Eysenck (1947, 1953).

It is clear, therefore, that primary suggestibility is an important trait in that it can be clearly differentiated from other traits, can be measured by a group of objective tests and is a reliable phenomenon. Its relationship to personality differences is, therefore, of great interest.¹

(b) Suggestibility and Personality

Early studies² considered that suggestibility is related to neuroticism but that it bears a special relationship to hysteria in that in this disorder an increased and exaggerated state of suggestibility can usually be found. However, Eysenck's researches showed conclusively that—

1. There is a close relationship between primary suggestibility and neurosis. In one study (Eysenck, 1944) one hundred and ten neurotics were compared with one hundred and ten normals (paired for Matrices I.Q.) on the Body Sway and Static Ataxia test. It was found that on the Body Sway test 63 per cent of male and 42 per cent of female neurotics were suggestible compared with 7 per cent of male and 8 per cent of female normals; sixteen neurotics fell outright, whereas no normal did. The correlation between primary suggestibility and neuroticism was 0.66.³ The study of Messer *et al.* (1938) found a correlation between amount of sway and tendency to give neurotic responses on the Bernreuter Inventory in normal subjects.

2. Later researches showed clearly that there is a strong correlation between amount of sway and amount of neuroticism. Fig. 2.2 shows the average amount of suggestibility (on a Body Sway test) for six groups of neurotic patients, a total of nine hundred and sixty males and three hundred and ninety females. It is clear that sway increases steadily with increase in severity of illness (Eysenck, 1947).

3. Contrary to the earlier suggestions in the literature, there is some evidence that while neurotics as a group are more suggestible than normals, dysthymics are most suggestible of all. Eysenck

(1947) reports that correlations between anxiety as a symptom and suggestibility are 0.26 for men and 0.33 for women, while for conversion hysteria the correlations are 0.12 for men and -0.08 for women. Figures for hysterical personality and anxious personality are similar.¹

FIG. 2.2. AVERAGE SUGGESTIBILITY OF NORMALS AND NEUROTICS, SHOWING INCREASE IN SUGGESTIBILITY CORRELATED WITH INCREASE IN "NEUROTICISM"

(From Eysenck, 1947)

4. There is some evidence that suggestible patients are of two kinds in relation to tests of primary suggestibility. On the one hand there are suggestible subjects who constitute an active, alert group; on the other there are suggestible subjects who constitute a passive, lethargic group (Eysenck, 1943). The similarity of these two groups to the overactive *v.* inert dichotomy found by Davis will be readily apparent.²

5. There is some evidence that catatonic schizophrenics are negatively suggestible; paranoid

¹ Benton and Bandura (1953) found no evidence for a general factor of primary suggestibility (average *r* of four tests = -0.07) in a group of fifty normal university students. Their conclusions are open to serious objection in that (a) they used a highly selected group, particularly with regard to I.Q. (all University students), although Eysenck had shown that subjects of average I.Q. are most suggestible; (b) such a group would certainly restrict the range of scores on suggestibility tests and hence lower the correlation; (c) although attempting to replicate Eysenck's results, they omitted the Heat Illusion test and replaced it with the Vibration test.

² Eysenck (1947) reviews these studies.

³ Since static ataxia tests (i.e. swaying without suggestion) discriminate powerfully between normals and neurotics, it is clearly necessary to allow for differences in "natural tendency to sway" in order to estimate the true effects of suggestibility. This was done by Ingham (1954, 1955) who confirmed the findings on body sway tests, even when differences in static ataxia were allowed for.

¹ An earlier study by Eysenck, however, (1943) using very carefully matched groups of conversion hysterics and dysthymics found no significant differences on primary suggestibility tests. Similarly Roach (1947) found no differences between introverted and extraverted normals.

² It does not seem to make any difference if hetero- or auto-suggestion is used (Baumgartner, 1931; Berremann and Hilgard, 1936; Eysenck, 1947).

schizophrenics positively suggestible; while manics are non-suggestible (Williams, 1932).

FINGER TREMOR¹

In this type of test, the intention is to measure the amount of involuntary movement which appears when the finger, hand, arm or body as a whole is held as motionless as possible. Static Ataxia and Body Sway have already been discussed. With regard to Finger Tremor, it has been found that schizophrenics have significantly greater finger tremor than normal (Edwards and Harris, 1953),² as have defectives (Edwards, 1950). Kellogg (1932) investigated the effects of emotional excitement upon muscular steadiness and found that those subjects who reported emotional upset were less steady than those who did not.

PERSEVERATION³

(a) *Dimensional Analysis of Tests of Perseveration*

Perseveration has been defined in somewhat different ways by various authors. Cameron and Caunt (1933) define it as "the tendency for an activity to persist after the subject has decided to change that activity, this persistence in the primary activity being shown by a transitory interference with the new activity which follows it." Jasper (1931) defined perseveration as "the tendency of a set of neurons, once excited, to persist in the state of excitation autonomously, showing resistance to any change in this state." Both of these authors stress the involuntary nature of perseverative activity.⁴

Other authors have preferred to stress the behavioural acts which may be said to define perseveration. Thus, Kleemeier and Dudek (1950) define flexibility (the obverse of perseveration) "simply as the ability (a) to shift from one task to another or (b) to break through an established set in order to perform a task," i.e. their definition makes no assumptions concerning brain processes (cf. Jasper above). Scheier and Ferguson (1952), similarly, define rigidity and flexibility in terms of negative transfer effects.

The concept of perseveration derives originally from clinical observations, which were first systematized by

Gross (1902) in terms of primary and secondary function. Primary function was defined by Gross as the *intensity* of any stimulus. The intensity of the primary function would determine how long it would persevere after the stimulus had been removed. The *duration* of the response was called the secondary function. An intense primary response would be followed by a long secondary response, a weak primary response by a short secondary response.

Gross then proceeded to relate type of function to type of personality, again basing his ideas on clinical experience. A person showing strong primary and long secondary responses would be deep-narrow (i.e. would suffer from a restriction of conscious awareness) or *introverted*; a person showing weak primary and short secondary responses would be broad-shallow (i.e. suffer from wide conscious awareness) or *extraverted*. The deep-narrow person would tend to persevere and have difficulty in switching from one task to another; the broad-shallow person would tend to flit from one subject to another and hence show little perseveration.

Most of the work carried out subsequently on perseveration derives directly or indirectly from the original work of Gross. Secondary function could manifest itself in at least four ways—

(i) the perseveration of a response after the stimulus has ceased, e.g. the length of time an after-image persists after the stimulus has been withdrawn.

(ii) the spontaneous reappearance of a response in consciousness after the original stimulus and response have both ceased. For example, a subject responding to successive stimuli A, B, C, D, etc., might respond with response A, to A; B, to B; C, to C, and then A, to D.

(iii) the extent to which the perseveration of a response to stimulus A *interferes with* (delays or prevents) the response to stimulus B, e.g. the extent to which writing S interferes with writing Z immediately afterwards.

(iv) the extent to which an ingrained (through repetition) response-habit interferes with a new response, although the interfering response may not itself be performed, e.g. mirror-writing.¹

The complicated nature and differing interpretations of perseveration tests may be shown by brief consideration of one of the simplest of such tests: the S-2 tests. In this test, three steps are usually taken—

(i) writing S as quickly as possible for 1 minute;

¹ It may be noted in passing that Gross postulated that the length of secondary function is directly determined by the *strength* of the primary function, i.e., there should be a high correlation between primary and secondary function. Most investigators have used *speed* of response as a measure of both primary and secondary function, not *strength*.

¹ Whipple (1924) has reviewed the earlier literature. Edwards (1946b) has discussed the factors influencing tremor.

² In an earlier study, Huston and Shakow (1946) found similar results, using two indices of steadiness. Their subjects were one hundred and thirty-five male schizophrenics and sixty-four normals (with repeated testing over time for forty-nine schizophrenics and twenty-one normals). However, they found no difference in steadiness if co-operative subjects only were compared.

³ Burri (1935), Rogers (1935a, 1935b), Kendig and Shevach (1937), Cattell (1946a, 1946b), Eysenck (1947, 1953) and Rim (1953) have reviewed this subject.

⁴ The involuntary nature of the perseverative process has been contrasted with the essentially voluntary nature of persistence and forms the principal distinguishing feature.

- (ii) writing 2 as quickly as possible for 1 minute;
- (iii) writing S2S2, etc., as quickly as possible for 2 minutes.

Such a test has been scored in a number of ways, each method intended as a measure of perseveration—

(a) The score (i — ii) may be regarded as a measure of the interference of the ingrained habit of writing S on a new, unfamiliar habit (such a measure may of course be obtained without (i) above being given at all).

(b) The score (i + ii) — iii may be regarded as a measure of the interference of writing S immediately before 2 and vice versa, compared with writing either S or 2 alone without interference.

Alternatively, the test may be given in the form—

- (i) writing S
- (ii) writing 2
- (iii) writing S

in which case (i — iii) would indicate the amount of interference of (ii) on (iii).

Cattell (1935a) attempted to elucidate the nature of perseveration by giving many different kinds of “p” tests and intercorrelating the scores. Stephenson (1934) had pointed out three kinds of “p” tests—

- (i) alternation tests;
- (ii) creative effort tests;
- (iii) direct “p” tests.

Using a large number of such tests Cattell intercorrelated the results obtained on fifty-two adults. As a result of this and later work he distinguished (1946a)—

(i) *Inertia of mental processes*, shown in “alternation tests” in which the subject has to switch to and fro between two interfering, alternate ways of performing tasks, the tasks being otherwise equivalent.

AAAA, etc.
BBBB, etc.
AB AB AB AB, etc.

Here the X and Y activities must follow in rapid temporal succession, producing interference by their momentum, inertia or after-effect.

(ii) *Disposition rigidity* or inertia of structural disposition. This shows itself in “creative effort” tests in which the score is measured as the difference between performing a task in some old, accustomed fashion and performing it in some new fashion, e.g.

SSSSS
22222

Here immediate temporal contiguity of the X and Y tasks is not essential, i.e. there is no question of inertia of functioning process.

Cattell argued that most of the published studies showed no evidence for the first type of perseveration; those which appeared to, did so because of the scoring technique—when this was corrected, no “p” factor was present. He concluded that there was a general factor proved only for motor “creative effort” tests and that this factor was best called “disposition rigidity.” He reported a study of his own in which six tests involving solely the “creative effort” principle and confined largely to motor performance tests were given to one hundred women students. From the resultant analysis, a general disposition rigidity factor emerged which accounted satisfactorily for the variance.

The conclusions at which Cattell arrived remained unchallenged for some time as they seemed to account adequately for most of the published findings. Thus Jasper (1931), using sensory and motor tests on normal subjects had found no evidence for an overall factor of perseveration but concluded that there was some evidence for the existence of a narrow group factor of motor perseveration. Jones (1928), using sensory, motor and ideational tests on manics and depressives, had found evidence in the test intercorrelations of a “general” factor covering ideational and motor tests in the melancholics but not in the manics. Pinard (1932a) had found evidence of a group factor covering tests of both the alternation and creative effort type (all motor tests). Rethlingshafer (1942) in a factor analysis of twenty-nine variables on normal college adults of high I.Q. found (among others) a factor she named perseveration which had significant loadings on six tests (time the subject worked at a task; length of time hand grip is maintained; preferred motor tapping rate; effect of a slower intervening rate on preferred rate of tapping; and answers to questions on the Maller-Elkin Attention test).

Notcutt (1943) gave a number of tests purporting to measure the four supposed kinds of perseveration (sensory; motor creative effort; motor alternation; associative, i.e. tendency for ideas to occur involuntarily). Of the eighty correlations between individual tests, thirty-nine were positive and forty-one negative, the mean $r = 0.005 \pm 0.011$, i.e. the results were precisely what would be expected by chance fluctuations in the scores. With regard to the four types, he concluded that there was no evidence for a factor of sensory perseveration; that the evidence for a creative factor was inconclusive; that the alternation tests had a mean r of 0.181 (if one test was omitted), indicating a genuine though very small common factor; and

that there was no evidence for associative perseveration. Nor did he find any correlation between the two motor groups of tests.

The situation was further reviewed by Walker *et al.* (1941, 1943) who concluded that the evidence for a general "p" factor was in all studies either decidedly negative or, at best, only weakly positive. They further pointed out that the tests used, by their very nature, made it impossible to distinguish (even if a general factor did exist) whether perseveration was due to mental inertia (as in the alternation-type test) or disposition rigidity (as in the creative-effort tests) since the latter usually entered into the former.

In spite of Cattell's efforts to elucidate the field, therefore, the evidence for either a general, or unrelated group factors, of perseveration remained extremely tenuous. However, a new light was thrown on the matter by Kleemeier and Dudek (1950) who carried out an obvious (but until then unthought-of) study. They used simple psychomotor tests which previous studies had shown would result by factorial analysis in numerical speed, perceptual speed and verbal factors. Within each set one task involved shifting. If these latter tests appeared on an independent axis in a factor analysis, there would be evidence for a factor of flexibility. Thirteen paper and pencil tests were used on two hundred and five college students. Four factors accounted satisfactorily for the variance. These were factors of perceptual speed, verbal, single-digit number, and two-digit number. The flexibility tests did not group themselves along an independent axis but could be accounted for in terms of the other factors. They concluded that "no factor of flexibility need be postulated to account for differences in performance on these simple alternation tasks."

While the study of Kleemeier and Dudek does not entirely solve the "riddle of perseveration" (they did not, for example, include any of the classical "p" tests) it does suggest that the classical "p" tests may be measuring factors other than perseveration and that a factor of perseveration, even if it genuinely exists, may contribute little to the total variance of the test. This conclusion was, of course, implicit in the previous findings which, even when positive, indicated a relatively unimportant factor and was supported by a recent careful study by Rim (1955). He used twenty-one tests of perseveration on both normal and neurotic subjects, and derived three factors of perseveration. With intelligence controlled, these factors were defined as—

(i) Disposition-rigidity, operating in motor and perceptual tasks—the rigidity of old-established habits in the presence of new demands.

(ii) Creative-effort rigidity—carrying out a new task never done before.

(iii) Cognitive or ideational rigidity—this was defined by tests similar to those used by Kleemeier and Dudek (1950).

The interesting point about Rim's study is that the amount of variance accounted for by the three factors of perseveration was as follows—

Factor I—	5·8 per cent
Factor II—	7·8 per cent
Factor III—	8·8 per cent.

These three factors together accounted for only about 23 per cent of the total variance of the tests, other factors and specifics presumably accounting for the remainder.

It would seem reasonable to suppose, therefore, that a combination of the approach of Kleemeier and Dudek on the one hand, and of Rim on the other would yield fruitful results. This was carried out, more or less, by Scheier and Ferguson (1952) who included tests of reasoning ability, cognitive rigidity, motor speed and motor rigidity in a battery given to sixty students. They identified three factors—

Factor A—a reasoning factor, involved in all tests to some extent.

Factor B—a motor speed factor with high loadings on the motor speed *and motor rigidity tests*.

Factor C—a non-motor rigidity factor.

However, they also concluded that "the motor rigidity tests used . . . have a factorial composition which is very largely reasoning and motor speed."

It seems reasonable to conclude from the evidence reviewed above that the most recent careful work confirms the existence of two forms of motor perseveration—alternation "p" and creative effort "p" (Rim, 1955); that these two factors nevertheless account for only a small proportion of the total variance attributable to the tests which are the best measures of perseveration (Rim, 1955); and that when suitable reference tests are included in a battery of perseveration tests, the amount of variance attributable to the factors of motor perseveration is negligible when compared with that attributable to other factors, especially the factor of motor (perceptual-motor) speed (Kleemeier and Dudek, 1950; Scheier and Ferguson, 1952).^{1,2}

(b) *Perseveration and Personality*

Many attempts have been made to relate the supposed factors of perseveration with personality factors. Early studies suggested that low "p" scores were characteristic of manics (Jones, 1928; Pinard,

¹ This conclusion is largely supported by recent work of Biescheuvel and Pitt (1955).

² More recently, interest has centred on the investigation of rigidity. The study of Cattell and Tiner (1949) suggested that rigidity is a kind of "ideational" perseveration, to be distinguished from "motor" perseveration.

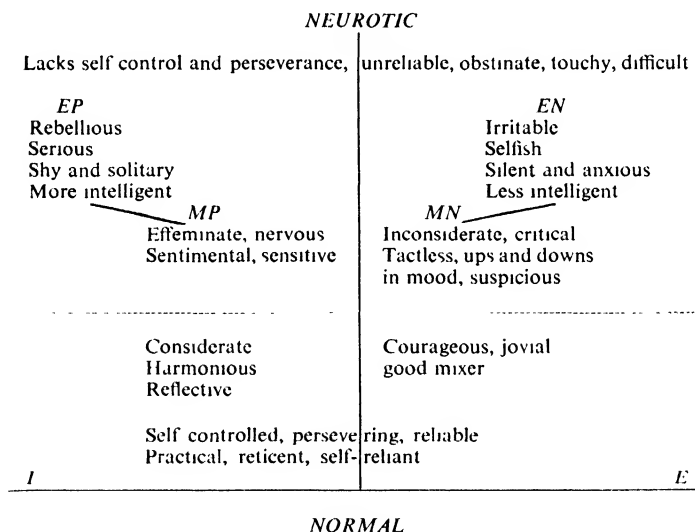

1932*b*; Stephenson, 1932*a*). High "p" scores, on the other hand, were said to characterize depressives (Stephenson, 1932*a*); schizophrenics (Pinard, 1932*b*; Stephenson, 1932*b*); stutterers (Eisenson, 1937); "emotionality" (Cattell, 1956) and various traits such as "youngest child in the family, being brought up indulgently, being more ailing as a child, being socially isolated, poorer prognosis with therapy" (Cattell, 1950).

In a series of studies Kendig (1937*a*, 1937*b*, 1937*c*, 1937*d*) found high "p" scores to be associated with induced failure in the task and with acceptance of the task as a test, rather than as a casual affair.

Jasper (1931) found effectively zero correlations between perseveration scores and introversion-extraversion scores (as measured by Conklin's E-1 Interest test); however, as he also found a significant correlation between introversion and depression it seems likely that this scale was measuring neuroticism rather than introversion.

perseverators. Thus, neurotics seemed to be abnormal perseverators, but to fall into two clear-cut and opposite groups.

In a later study (Pinard, 1932*b*) he attempted to relate perseveration to introversion. Patients were interviewed and rated themselves on a scale covering all points related to introversion by previous investigators. He found that "the extreme perseverators and non-perseverators have in common lack of self-control and perseverance to a marked degree and they are unreliable, obstinate, 'touchy' and difficult. They differ from each other in that the extreme perseverator tends to be effeminate, 'nervous,' sensitive, sentimental, serious, shy and solitary, whereas the extreme nonperseverator tends to be suspicious, inconsiderate, critical, impatient of criticism, tactless, silent and anxious and in a state of general tension with ups and downs in mood." Pinard's diagram summarizing his findings resembles Eysenck's dimensional system very closely.

In his first study Pinard (1932*a*) appeared to relate extreme "p" scores to different types of neurosis. Thus, in a study on children, he found that 75 per cent of the most difficult and unreliable children were either over- or under-perseverators while the opposite was true of the self-controlled children, i.e. they showed moderate perseveration. The extremely perseverative children were the real rebels, irritable, bad-tempered and moody; the non-perseverators were "petty," nagging and whining.¹ These results were confirmed for adult neurotics, 75 per cent of the most difficult and unreliable patients being over- or under-

Notcutt (1943) found a correlation of only - 0.03 between alternation "p" scores and introversion, using normal subjects, but this is not surprising since he found no clear-cut factor of perseveration.

Cattell (1946*b*) found a negative correlation between "w" and "p" in neurotics, supporting the earlier finding by Brogden (1940) whose first factor was identified as one of perseveration and was said by Brogden to bear "a considerable resemblance to Webb's 'w' factor." This would suggest a relationship between perseveration and neuroticism (since Eysenck (1953) has shown that Webb's "w" factor is the normal pole of a normal-neuroticism dimension).¹

¹ Also using children (delinquents and normals), Clarke (1934) concluded that extremes of perseveration are associated with opposition to authority.

¹ Weisgerber (1954) has also related perseveration to neuroticism.

However, Cattell also found that "p"-scores were negatively correlated with his own E-factor (Dominance-Submission) which seems to be similar to Eysenck's I-E factor (Eysenck, *The Structure of Human Personality*, p. 64, 1953). In a further study on two hundred men and one hundred women, the correlation between dominance and rigidity was -0.44 . Furthermore, he found, like Pinard, that the relation of "p"-score to dominance was curvilinear—

He concludes that "the factor of rigidity . . . is simply a relative inability to mould old habits, in one performance, to new ones . . . this means slowness of learning under the usual conditions of repetition of training . . . we shall assume that rigidity means a general slowness of learning." This *schema* also fits closely Eysenck's recent formulations characterizing the *introverted* neurotic as a rapid learner or over-socialized and the *extraverted* neurotic as a slow learner, or under-socialized. Cattell's final position, however, is far from clear.

It is clear from the definitions of primary and secondary function and their relationship to the deep-narrow and broad-shallow personality types that it would be predicted that high perseveration would be characteristic of introversion and low perseveration characteristic of extraversion in Eysenck's dimensional system; and that such a pattern would be expected to be found in normal subjects as well, since it is characteristic of introverts and extraverts, rather than neurotics. The findings of Cattell (1946b) and Pinard (1932b) in particular appear to support this hypothesis, especially in their suggestion of a curvilinear relationship indicating distinct groups of high and low perseverators.¹

However, the careful study by Rim (1955) failed to reveal any evidence of a non-linear relationship between perseveration and neuroticism; failed to reveal any significant differences among neurotic subgroups which included hysterics and psychopaths, anxiety states and obsessives, and a mixed group of neurotics; and failed to reveal any correlation between perseveration and neuroticism on the one hand, or between perseveration and introversion-extraversion on the other. Similarly Petrie (1948) found no differences between hysterics and dysthymics on four tests of perseveration.

¹ Misiak and Pickford (1944), however, found results diametrically opposite; asthenic boys tended to be *low* perseverators; pyknic boys *high* perseverators.

We must, therefore, conclude that factors of perseveration are of little importance in defining differences either between neurotics and normals or between extraverts and introverts. This is not surprising in view of the small amount of variance of the tests used to measure perseveration accounted for by the factors.^{1,2}

FLUENCY³

Fluency tests constitute a classic example of the ideomotor type of psychomotor test, i.e. a verbal response following upon an "idea." The principal findings with respect to tests of fluency may be summarized as follows—

(i) The major variance of a battery of fluency tests can be accounted for by a general factor, which Rogers (1953) identifies as "g" plus Vernon's "v: ed" factor (verbal-educational).

(ii) Two orthogonal factors (in addition to the general factor) have been identified by Rogers (1953). The first factor is one of *oral* fluency; the second, a factor of *written* fluency. In independent studies, Rogers (1953, 1956) found that these three factors were extraordinarily stable, both as regards the tests which define them and the factor loadings of these tests.

(iii) Two further factors have been suggested by Rim (1955). One factor in his study defined three tests of oral verbal fluency where relatively *less constriction* is given in the instructions, viz. "towns," "trees" and "animals." This factor is the same as Rogers' factor of oral fluency. Rim's second factor defined three tests of oral verbal fluency where *more constriction* was given in the instructions, viz. "first letter A," "suffix -ion," and "anagrams." This factor is similar to a factor found by Rogers (1953) which he defined as "dealing with words in which one or more formal restrictions were placed on the response." The factor, however, cuts across the previous factors of oral and written fluency, since Rogers's study showed it was defined by both oral and written tests.⁴ These results agree with earlier studies by Carroll (1941), Gewirtz (1948) and others.

(iv) Psychotics are significantly less fluent than either normals or neurotics. S. B. G. Eysenck

¹ Mittenecker (1953) has recently proposed a new method for measuring perseveration, which is applicable to spoken or written language, 500–1,000 syllables in length; and has analysed the productions of cyclothyme and schizothyme normals, and psychotics.

² A similar conclusion was arrived at by Walker *et al.* (1945) and by Yule (1952), partly as a result of a logical examination of the nature of "p" tests and partly on the basis of the results of studies reviewed above.

³ See Vernon (1950), Eysenck (1953), Rim (1953) and Rogers (1953, 1956) for reviews of the literature.

⁴ Rim (1955) used only *oral* verbal tests.

(1955) found psychotics significantly poorer than either neurotics or normals (using three tests of relatively *less* constriction); while Eysenck (1952a) found similar results in a comparison of psychotics and normals only.

(v) The evidence for neurotic's being less fluent than normals is of doubtful significance. S. B. G. Eysenck (1955) found that they were, but to a much less degree than psychotics; while Rim (1955) could find no differences between normals and neurotics on six tests of fluency.¹

(vi) Earlier suggestions that fluency may be related to differences in introversion-extraversion have not been confirmed. Petrie (1945) found no differences in fluency between hysterics and dysthymics, nor did Himmelweit (1946) and Rim (1955). Petrie (1945), however, did find that hysterics tend to make more *errors* than dysthymics under appropriately controlled test conditions.²

While the existence of various factors of fluency has clearly been demonstrated, therefore, it must be concluded that they have not been very useful in the analysis of differences in behaviour of different psychiatric groups.

PERSISTENCE³

(a) *Dimensional Analysis of Persistence Tests*

Like perseveration, persistence tests have been subjected to a great deal of experimentation in an effort to discover whether a unitary factor of persistence can be demonstrated or not. Much of the work has been unsatisfactory and inconclusive but on the whole appears to point to the existence of a general factor. However, the position was clarified considerably by the work of MacArthur (1951).⁴ He intercorrelated twenty-two measures of persistence from which the influence of intellectual differences had been partialled out; 75 per cent of the correlations were positive, with 29 per cent significant. A factor analysis using simple structure revealed four factors: (1) a general persistence factor;⁵ (2) a bipolar factor contrasting individual with group (prestige) persistence; (3) a bipolar factor contrasting reputation for persistence with objective evidence of persistence; (4) a factor of

persistence in a group of physical tests—holding foot over chair (leg persistence), maintained hand-grip (dynamometer), time of holding breath, and arm extension.

This last factor is relevant to the present chapter since it is measurable by tests of a psychomotor nature, particularly leg persistence and maintained hand-grip. The existence of such a factor has been demonstrated by other writers in addition to MacArthur. Thornton (1939) described a factor of "ability and/or willingness to withstand discomfort in order to achieve a goal" with high loadings on "time holding breath," "time standing shock," "time standing pressure," "maintained hand-grip."¹ Likewise Rethlingshafer (1942) described a factor of "willingness and/or ability to endure discomfort." As Eysenck (1953) points out the group factors of persistence demonstrated by MacArthur "are subject to measurement with a degree of validity probably not much below general persistence itself."

(b) *Persistence and Personality*

1. *Leg Persistence*: This test has been most commonly employed in studies with abnormals. The test is a very simple one, the subject usually being required to hold the leg outstretched one inch above the seat of a chair for as long as he can. The results obtained are conflicting and may be summarized as follows—

(i) Careful studies have shown that neurotics are not differentiated from normals in terms of persistence. Thus Eysenck (1952a) compared several groups of neurotics with normals; although all the neurotics had *lower* mean scores than the normal group, the differences were not significant. Similarly, S. B. G. Eysenck (1955) compared neurotics with normals and found no difference, as did Himmelweit and Petrie (1951) with neurotic and normal children. Ryans (1939) concludes from his review of the literature that non-persistent subjects "may show more pronounced leanings towards neuroticism and introversion than persistent persons" (introversion here is probably to be equated with neuroticism). However, this conclusion cannot be said to apply to motor persistence.

(ii) Several studies also suggest that there are no significant differences between hysterics and dysthymics on leg persistence (Eysenck, 1952a; S. B. G. Eysenck, 1955). Petrie (1948) on the other hand, found that dysthymics persevered over twice as long as hysterics.²

¹ Thornton did not think that this was a true persistence factor though he considered it might be related to persistence.

² Test instructions appear to play an important role in leg persistence tests. Thus S. B. G. Eysenck's (1955) neurotics showed very much greater persistence than did those tested by Petrie and Eysenck; but in the S. B. G. Eysenck (1955) study, the subjects were allowed to flex the leg if they wished.

¹ Unfortunately, Rim's control group was small (N = 25) and rather unsatisfactory in its composition. Eysenck's (1955) results may be more reliable, therefore, in indicating a small but significant difference between neurotics and normals.

² In a recent study, Rogers (1956) found a significant relationship between fluency in dealing with words and Eysenck's introversion-extraversion factor. This finding would not appear to vitiate the conclusions arrived at above.

³ See Ryans (1938a, 1939), Kremer (1942) and Eysenck (1953) for reviews of this topic.

⁴ A detailed account of MacArthur's unpublished thesis is contained in Eysenck (pp. 288-290 *op. cit.*).

⁵ Crutcher (1934) and Ryans (1938b) also found a general factor of persistence.

(iii) Eysenck (1952*a*) found no differences between normals and psychotics in leg persistence.

2. *Dynamometer Persistence*: In this test, strength of grip is usually measured first and the subject then required to squeeze for as long as possible at half or two-thirds the maximum strength.

The major findings with this test are as follows—

(i) S. B. G. Eysenck (1955) reported that neurotics showed significantly less persistence than normals. As, however, the neurotics showed a much weaker initial maximum grip, it is possible that this affected their subsequent persistence. Similar results for normal *v.* neurotic children were reported by Himmelweit and Petrie (1957).

(ii) No comparisons are available for dysthymics and hysterics separately.

(iii) S. B. G. Eysenck (1955) also reported that psychotics showed significantly less persistence than normals (with the same reservations as to initial strength of grip). The psychotics did not differ from the neurotics in persistence.

WORK DECREMENT¹

The "curve of work" (Thorndike, 1912) (i.e. the changes occurring in performance under conditions of prolonged performance of mental or physical work) has mediated a large amount of research on normal subjects. The work studied may be either physical in nature (e.g. ergographic) or "mental" (e.g. continual addition, naming colours, etc.). Among the major trends noted in the objective work curve are (*a*) warm-up effect; (*b*) practice effect; (*c*) spurts and rhythms; (*d*) general (work) decrement; (*e*) blocking. The two latter phenomena are of particular importance. Work decrement refers to the decline in amount of work done per unit time during a period of continuous practice. Blocking refers to temporary complete stoppages of work under the same conditions of practice. Such blockages and work decrements have been observed in both physical and mental work but are more easily observed in the former since the phenomena appear to be directly related to the lack of rest pauses. Such rest pauses are naturally more common in "continuous" physical work than in "continuous" mental work. However, under appropriate conditions of forced continuous mental work (such as naming colours) the involuntary blockages can be readily observed.

Both phenomena have been considered to be functions of fatigue² induced by continuous work.

Blockings could be obviated by enforcing rest pauses at about the same rate; while they could be increased by making the material more homogeneous. Thus, where conditions of work were most homogeneous, the average blocks per minute were 2.1; where they were least homogeneous, only 1.4 per minute (Robinson and Bills, 1926).¹

The phenomena involved in the work curve have, of course, long attracted the attention of psychologists (Thorndike, 1912). However, little attention has been paid to the possibilities such phenomena offered in the investigation of abnormal subjects. Apart from the early work of Kraepelin (1902) and Hoch (1901) little information was available until very recently. Kraepelin had found that the performance of schizophrenics on a simple ten-minute addition test was characterized by rapid deterioration; if a rest was introduced after five minutes, performance increased markedly on the sixth minute, but then deteriorated rapidly again in the remaining four minutes. Hoch, on the other hand, reported that manic-depressives increased in strength of performance on the ergograph in the early stages of performance before showing the usual fatigue effects.

Since these early studies, little work has been done in this field. Mailloux and Newburger (1941) presented patients with a task involving four coloured lights with corresponding keys. Depression of the appropriate key extinguished a light and served to activate another. Thus continuous work was carried on for ten minutes. Patients were classified into six groups according to speed and type of response activity. Compared with the normal rate of seventy-two responses per minute, psychotics averaged a response rate of only 52.5, only one psychotic exceeding the normal mean. Psychotics averaged five blocks per minute compared with three for the normal group. Mailloux and Newburger found no relationship between work curve and blocking on the one hand and type of psychosis on the other.

More recently, using a very similar method, Venables and Tizard (1956*c*) and O'Connor *et al.* (1956) have repeated the study of Mailloux and Newburger. Venables and Tizard found an initial rise in performance (probably due to practice effects) followed by a fall, a further rise after rest and subsequent deterioration in schizophrenics. Long-stay schizophrenics performed consistently below short-stay schizophrenics at all stages of performance. A group of endogenous depressives were intermediate between the two schizophrenic groups but showed no

¹ See Bills (in Andrews *Methods of Psychology*, Chap. 16, 1948), and Robinson (1934) for excellent reviews of this subject.

² It has been shown conclusively that such "fatigue" is not entirely peripheral, i.e. muscular.

¹ The main work on this topic has been carried out by Bills (1931, 1935, 1937, 1943), Bills and Shapiro (1936), Robinson (1926), Robinson and Bills (1926). See also Poffenberger (1927), Freeman and Wonderlie (1935), Warren and Clark (1937), Huxtable *et al.* (1946) and Philip (1939*a*, 1939*b*, 1939*c*, 1940).

deterioration in performance, either before or after the rest pauses.¹

It seems clear, therefore, that schizophrenics do show blockings and rapid work decrement compared

with normals. This conclusion is supported by a recent study of Baruk *et al.* (1953). No information is available concerning the performance of neurotics.¹

III. DISCUSSION

THE bewildering and often contradictory results brought together above do not mediate any obvious theories concerning the behaviour on psychomotor tests of neurotics and psychotics as compared with normals. For reasons which will be discussed below this is not surprising. However, some tentative suggestions will be made concerning possible reasons for those differences which are generally clear-cut.

Four relatively definite statements may be made concerning the psychomotor behaviour of abnormals and normals.

1. Compared with normal subjects, neurotics show no significant disorganization on *simple* psychomotor tasks (and may actually be better than normals). They do, however, show marked disorganization compared with normals on *complex* psychomotor tasks. This disorganization is not a function of lower intelligence or poorer special abilities.²

2. Within the total neurotic subgroup, there is evidence that introverted neurotics (i.e. dysthymics) show a different kind of motor disorganization compared with extraverted neurotics (i.e. hysterics); this difference is found also in normal extraverts and introverts.

3. Compared with normal subjects, psychotics show significant disorganization on both *simple* and *complex* psychomotor tasks.

4. There is some evidence that psychomotor tests which discriminate best between neurotics and normals are different from those which discriminate best between psychotics and normals, i.e. that psychosis and neurosis represent different dimensions.

In the following discussion, four important points should be borne in mind—

1. The differences outlined above refer to differences in *performance*, not to differences in *learning*. This distinction has become an important matter in theories of behaviour in recent years. The frequent failure to control for differences in learning ability

before measuring differences in level of performance (i.e. when learning has been maximized) is extremely unfortunate and has undoubtedly contributed to much of the confusion prevailing in this field.

2. The method adopted above of summarizing the main findings in terms of type of response required (e.g. reaction-time, tapping, etc.) was dictated by the prevailing method of experimenting on two groups by comparing their performance on a single task. This method is particularly inappropriate in this field, since psychomotor tests are often short and correspondingly unreliable. It is extremely dangerous, therefore, to draw conclusions from studies using a single test. Psychomotor tests should be used as one strand among others in the investigation and testing of theories concerning abnormalities of behaviour. They can rarely be used satisfactorily on their own.

3. A major difficulty in interpreting the results of diverse studies in relation to a given theory is that the analysis of results of earlier studies may be quite inappropriate. A good example of this is the interpretation of the work of Davis (1948) outlined above. Davis showed that introverted neurotics gave a characteristically different kind of manual response as compared with extraverted neurotics. Now it would seem reasonable to suppose that similar results would be expected from the Luria (1932) test. Unfortunately, although much valuable work has been done on the Luria and although it is clear that neurotics do show motor disorganization in this test, it is difficult from the earlier studies to determine whether introverted and extraverted neurotics showed different kinds of responses comparable to those found by Davis, since no precise analysis of this kind has been carried out.² Thus it is possible only to point out that such differences would be expected if the Luria results were analysed in a particular way.

4. Very similar to this difficulty is the problem of negative results. The often repeated dictum that one negative result invalidates a theory is only a half-truth. It is true only if the experiment is sufficiently precisely controlled that a negative result will have an unequivocal interpretation. Now this is seldom true in the field of psychology. Let us suppose our theory

¹ This study of Venables and Tizard is open to serious criticism on the grounds of a failure to separate their endogenous depressive group into a short-stay and long-stay group. It is possible that, had they done so, the performance of the two groups would have been similar to those of the short-stay and long-stay schizophrenics, in which case the effects obtained could be due to either (a) length of stay; (b) psychoticism as such; or (c) an interaction of these two variables.

² Psychomotor tests have proved among the most useful measures for defining the factor of "neuroticism" by factorial methods. See, for example, the study by Himmelweit *et al.* (1946).

¹ The study by Christensen (1945) on neurotics has not been available for consultation.

² As pointed out earlier, several studies do, however, suggest that such differences exist

predicts that extraverted neurotics will have a slower rate of tapping than introverted neurotics due to the more rapid growth of reactive inhibition in the former group. The analysis of the results in terms of number of taps per unit time may show no significant differences between the groups. This does not necessarily mean that the hypothesis has to be abandoned. The failure to find significant differences may be in the method of analysis adopted. A study by Boder (1935) is relevant. He showed that even such a simple activity as tapping has at least four components (movement up, upper reversal, movement down and bottom reversal). By means of oscillograph recordings he found that between both progressions there is a definite stop, which, in finger tapping, lasts from twice to four times as long as the progressions. He found that concomitant activities led to reduced speed, alterations in pattern of tapping, *differences in duration of arrested movement*, and reduction in tapping excursion. Now it is possible that taking an overall tapping rate as score on this test obscures significant differences in duration of arrested movement since extraverted neurotics may well "catch up" on other aspects of performance. In other words the prediction is relevant only to one aspect of performance and failure to isolate that aspect may lead to negative results in relation to the theory. This point should be remembered in all instances where negative results are obtained, especially where the theory is supported by other evidence.¹

With these cautions in mind a brief review will be given of some theories which have been advanced to explain the results summarized above.

Psychomotor Performance of Neurotics

The following postulates help to account for the observed differences between neurotics and normals in psychomotor tasks and mediate new predictions which support the general theory—

1. Performance in the test situation may be conceptualized as dependent upon the interaction of drive strength and task complexity.²
2. Neurotics are characterized by high drive.
3. High drive may also be defined in terms of the strength of a stimulus. Thus a strong stimulus will have high drive value; a weak stimulus low drive value.³

¹ Similarly, Earle and Gaw (1930) analysed manual and finger dexterity into three types of movement.

² This is, of course, a reformulation of the Yerkes-Dodson law (Yerkes and Dodson (1908); Dodson (1915)) that the optimum intensity of drive (shock) varies inversely with the difficulty of discrimination.

³ The second postulate could also be written in these terms, i.e. that high drive in neurotics means that a stimulus having low drive value for normals will have high drive value for neurotics.

4. Where the response required is simple, it will be facilitated by high drive.

5. Where the response required has to be chosen from among others (i.e. discrimination is involved), it will be impeded in its appearance by high drive.

The above postulates would mediate the following predictions—

(a) Neurotics will show psychomotor disorganization compared with normal subjects on complex but not simple tasks. The evidence in favour of this has been reviewed at length above.

(b) An increase in the strength of the stimulus will lead to an increased amplitude and speed of response in normal subjects. This prediction has been abundantly verified particularly in the field of reaction-time studies. Thus Johnson (1922) in an early study showed that increasing the strength of the stimulus led to a faster R.T., as did Chocholle (1945); Steinman and Veniar (1944) found that faster reactions to a constant stimulus ratio were obtained at the stronger of two levels of visual intensity. Higher muscular tension levels (Travis and Kennedy, 1947), increased motivation (Hipple, 1954) and mild electric shock (Henry, 1951) all facilitate speed of simple reaction-time. Above a certain intensity, however, a stimulus ceases to facilitate response and begins to inhibit it. This was shown by Johnson (1922) and by Pascal (1953) who found that when a loud disturbing noise was given with the ready signal for reaction-time, some subjects showed complete disruption of performance. This result would be expected from the Yerkes-Dodson law since it specifies *optimal* levels of intensity for most adequate performance.

Henry (1951) also showed that mild electric shock significantly speeded up speed of snatching a ball and speed of treadle pressing.

(c) An increase in induced anxiety in normals (usually by means of some stressful situation) will facilitate amplitude and speed of simple responses.¹ Thus, Ross *et al.* (1954) found that speed of tapping increased significantly with an increase in anxiety just before the subject engaged in a boxing match. An important study relevant here is that by Castaneda (1956) which links anxiety as drive and stimulus intensity as drive. His subjects were high- and low-anxiety² high-school boys and girls; the stimulus a buzzer with two intensities; the response, squeezing a dynamometer; and the scores recorded, amplitude and speed of reaction. On the theory

¹ There is no clear-cut division between this section and the previous one. See Lazarus *et al.* (1952) for a discussion of the effects of stress upon performance.

² Determined by scores on the Taylor Anxiety Scale (Taylor, 1953) which Franks (1956) has shown is mainly a measure of neuroticism.

that differences in intensity produce differences in relevant drive and differences in anxiety produce differences in irrelevant drive he predicted that (1) speed of reaction of anxious subjects should be faster than that of non-anxious subjects; and (2) the increase in speed of reaction attributed to increased stimulus intensity should be relatively greater for non-anxious subjects, thus reducing the difference between anxious and non-anxious subjects. With regard to amplitude Castaneda found that anxious subjects did indeed show significantly higher amplitude at weak intensities and that there was a greater increase with the more intense stimulus in non-anxious as compared with anxious (though the latter finding held only for boys). With regard to speed of reaction, Castaneda found no difference at the weaker intensity between anxious and non-anxious subjects and contrary to prediction found a greater increase in speed at the higher intensity for the anxious subjects.¹

(d) Whereas increasing stimulus strength, inducing anxiety or stress in normals appears on the whole to facilitate response amplitude and speed in normals where the response required is simple in nature, it is predicted from the theory that the same factors would disrupt performance where the response required had to be selected from a range of possible choices or where the response itself is of a complex nature. There is a reasonable amount of evidence indicating the correctness of this prediction. Thus, a study by Grice (1955) indicates a significant increase in discrimination response time under conditions of induced anxiety or stress² and this is supported by the work of Patrick (1934a, 1934b).

Several studies on induced conflict (stress) indicate that "the probability of blockage as a reaction to conflict increases with the approach of the strengths of the conflicting responses to equality" (Sears and Hovland, 1941) and this conclusion is supported by several other studies (Hovland and Sears, 1938; Cartwright, 1941a, 1941b; Festinger and Wapner, 1947).

Similarly, it has been shown that complex motor reactions deteriorate markedly under stress in normal subjects. This holds for steadiness (Edwards, 1948; Kellogg, 1932; Parsons *et al.*, 1954; Seashore and Koch, 1938; Ross *et al.*, 1954); the work curve

(Burghmann, 1939) and more complex tasks (Lofchie, 1955; Russell, 1932; Starer, 1942; Hill, 1954; Canestrelli, 1941).

Thus we may reasonably conclude with Davis (1947) that in normal subjects "under conditions . . . in which . . . anticipatory tension was increased, skilled responses were more extensive, more precipitate, more disturbed by restless movements and less accurate than single conditions (simple stimuli) in which anticipatory tension was normal." The above results and those reported in the body of the chapter do seem to support the hypothesis that neurotics are characterized by a high state of drive which facilitates the correct response in a simple situation but impedes the correct response in a complex situation.

Psychomotor Performance of Introverts and Extraverts

Little can be said about this aspect of performance in psychomotor tasks, except to repeat that it seems to be clearly established that the *type* of motor response on a given task will differ for extraverts as compared with introverts where the appropriate experimental conditions are set. Within the neurotic disorganization apparent on complex tasks, hysterics will tend to react differently as compared with dysthymics. The main evidence for this proposition derives from the work of Davis (1946a, 1946b, 1947, 1948, 1949a, 1949b), which has been discussed above in detail, but similar differences could no doubt be obtained on tests such as those of the Luria, under appropriate conditions.¹

That there are two major types of psychomotor response within both normal and neurotic groups is also suggested in the work of Chorus (1942, 1943) on abnormal children (that arising from diffusion of attention and that arising from lethargy); Fauville *et al.* (1937) (who distinguished the impulsive from the precise mode of motor reaction); Schleier (1939) (who distinguished extraverted from introverted types of movement); and Yarmolenko (1930) who distinguished the excitable type of child (rapid irregular movement) from the inhibited type (slower, more regular and more intense motions). The similarity of these types to those of Davis is clear.

Eysenck (1955) has postulated that differences between introverts and extraverts are due to differences in the rate of growth, magnitude and persistence of reactive inhibition, hysterics being characterized by rapid growth of inhibition, dysthymics by slow growth of inhibition. A number of experiments are reported by him which support this hypothesis, as does work by Broadbent (1953, 1956), including his interpretation

¹ Similar studies have been carried out by Wenar (1954) and Farber and Spence (1956) with conflicting results. They indicate neatly the problems involved in testing hypotheses of this nature. Thus, in the work of both Castaneda, and Farber and Spence, two major problems make negative results difficult to interpret, i.e., the adequacy of the strength of the anxiety (induced or otherwise) and the adequacy of the differences in intensity of stimulation.

² Grice, however, attributes the differences between his high and low anxiety groups to differences in intelligence.

¹ Descriptively, Davis's differentiation of hysterics as "inert" and dysthymics as "overactive," corresponds with Himmelweit's (1946) differentiation of hysterics as preferring speed to accuracy from dysthymics as preferring accuracy to speed.

of the results of Mackworth (1948) on errors in continuous watch-keeping. However, Eysenck's specific predictions made on the basis of his inhibitory-excitatory potential differences in extraverts and introverts have not so far included psychomotor tests. These tests would, it is clear, be eminently suitable for precise predictions in terms of the theory, particularly those tests involving continuous performance such as is involved in the study of the work decrement. There is here a rich field of investigation, which remains to be explored.¹

Psychomotor Performance of Psychotics

Three explanatory models will be mentioned and briefly discussed in connexion with the psychomotor performance of psychotics.

1. The dissociative-integrative hypothesis of Kretschmer has mediated a large amount of experimental work.² By dissociation Kretschmer means the ability to form separate and partial groupings within a single act of consciousness; from this results the ability to dissect complex material into its constituent parts. Normal schizothymes (and schizophrenics) are said to be characterized by dissociative capacity; normal cyclothymes (and manic-depressives) by integrative capacity. In efforts to demonstrate the validity of this thesis, Kretschmer and his students made extensive use of psychomotor tests. Thus, on the basis of the theory it was predicted (and experimental evidence was brought forward in support) that leptosomes³ would be superior to pyknics in the following tasks—

(a) Simultaneous performance on more than one psychomotor task, e.g. addition of numbers and calling out of numbers (Enke, 1928; Enke, 1930; Gurewitsch and Oseretzky, 1930; Schorn, 1928).⁴

(b) Motor activities, e.g. manual dexterity, quality of handwriting, bimanual co-ordination, fine steadiness test (Enke, 1929, 1930).

¹ It seems likely that research in this field will prove to be extremely complex. Thus, in the simple leg persistence task, performance may be a function of at least two drives and rate of growth of inhibition in neurotics. Hence, dysthymics will have a strong drive to avoid discomfort, a strong drive to carry out the instructions, and a slow rate of growth of inhibition; while hysterics would have a strong drive to avoid discomfort, a weak drive to conform with instructions and a rapid growth of inhibition.

² The literature has been reviewed in detail by Eysenck (1950) and by Payne (1954), the latter with respect to the hypothesized trait of *Spaltungsfähigkeit*.

³ As Eysenck (1950) points out, Kretschmer tried to show the general validity of the concept of schizothymia-cyclothymia beyond the psychotic realm by using body build as a *tertium quid*; his method of proof was to show that normal people of leptosomatic or pyknic body build react to certain psychological experiences in a manner similar to that of schizophrenics and manic-depressives, who are known to be also leptosomatic or pyknic.

⁴ Schorn's study was one of the few of Kretschmer's school which obtained negative results.

(c) Speed of motor activity, e.g. tapping (Enke, 1930).

(d) Speed of reaction-time under distraction (Kibler, 1925; Van der Horst, 1924).

Subsequent work, however (which overcame most of the obvious defects of the above studies, such as lack of statistical analysis of results, tests of significance and control of relevant factors such as sex, I.Q., age, etc.) has refuted Kretschmer's theory. Two lines of evidence may be quoted.

(i) Payne (1954) has shown conclusively that the tests used by Kretschmer as a measure of dissociative differences between schizothymes and cyclothymes do not define a factor of "dissociation" (the correlations between a large number of measures, including many specified by Kretschmer and others derived from the theory, clustered about zero and were distributed in accordance with the null hypothesis that there was no general factor). Hence it follows that these tests cannot be used to support Kretschmer's hypothesis and, indeed, refute it as an explanatory principle.¹

(ii) In a number of studies, Eysenck (1952*a*, 1952*b*) has shown that there is no evidence for the existence of a dimension of cyclothymia-schizothymia, such as is required by Kretschmer's theory; but that there is evidence for a dimension of psychoticism-normality. In other words, on tests of the type used by Kretschmer, manic-depressives do *not* tend to fall at one end of a distribution of scores, schizophrenics at the other, and normals in the middle, as would be expected if Kretschmer's theory were correct. Rather *both* manic-depressives and schizophrenics tend to do *worse* than normals on those tests which distinguish the three groups, with schizophrenics falling in between normals and manic-depressives.

It would seem, therefore, that Kretschmer's concept of "dissociation" must be abandoned as an explanatory principle and research directed towards the solution of the problem that psychotics as a whole perform more poorly than normals on certain psychomotor tests.²

2. A hypothesis which has received surprisingly little attention since it was originally proposed is that of Shakow (1946) and his colleagues who account for

¹ This is not, of course, to say that the *differences* found by Kretschmer between e.g. schizophrenics and manic-depressives do not exist; but simply that such differences cannot be accounted for in terms of the postulated mode of reaction.

² But not on all such tests. As Eysenck (1952*a*) has shown, "those tests which had in past work been shown to have high correlation with neuroticism, or to discriminate well between neurotics and normals, do not show even a tendency to discriminate between normals and psychotics." Such tests include persistence, body sway, perseveration and work curve inversions.

the poor performance of schizophrenics on psychomotor (and many other) tests in terms of failure of set. Table II.11 shows the results obtained for two groups of schizophrenics (selected and total) and normal controls on tests of steadiness, tapping, reaction-time (simple auditory and discriminatory visual) and prodmeter which illustrates quite clearly the highly significant results obtained. With regard to differences obtained under conditions of regular and irregular preparatory intervals in the reaction-time

3. Three recent studies by Venables and Tizard (1956*a*, 1956*b*, 1956*c*) have attempted to account for differences between schizophrenics and normals in terms of the growth of reactive inhibition. They base their hypothesis chiefly on the work of Pavlov (1941) who showed that dogs with weak inhibitory, nervous systems in whom pathological disturbances of the cortex are induced by means of functional interference tend to respond to conditioned stimuli with "paradoxical" responses (in which weak stimuli call forth a

TABLE II.11
SCORES OF SCHIZOPHRENICS AND NORMALS ON PSYCHOMOTOR TESTS

(From D. Shakow, "The Nature of Deterioration" 1946)

Variable	Normal			Total Schizophrenics			Selected Schizophrenics			CRs		
	N	M	σ	N	M	σ	N	M	σ	N/TS	N/SS	TS/SS
Steadiness score	64	120.0	65.1	135	62.3	54.3	25	67.9	42.5	6.1	4.5	0.6
Tapping mean	60	28.9	4.2	125	19.5	5.6	25	21.4	5.2	13.2	6.7	1.7
R.T. Simple auditory	25	167	30	38	357	182	25	325	54	5.5	12.6	1.0
Discriminatory visual	25	373	51	38	676	253	24	627	258	5.8	4.1	0.7
Prodmeter time	62	24.6	3.2	125	34.9	12.0	24	31.5	6.0	8.0	5.5	1.5
Errors	62	32.6	4.1	125	43.0	14.6	24	43.6	7.1	7.5	7.0	0.3

experiments, Rodnick and Shakow (1940) concluded: "Although the patients are able to maintain a comparatively high preparatory set during the shorter intervals of the regular as compared to the irregular procedure, they have greater difficulty than do normals in maintaining the advantage. As a result they fall back upon a lower level of preparation at the longer intervals. This simpler adaptive level is essentially the same as that used in reacting in the irregular procedure, the conditions of which do not favour an optimal level of response." The Set Index derived by Rodnick and Shakow from their results discriminated without overlap between schizophrenics and normals in that study.

Recently Tizard and Venables (1956) repeated the work of Rodnick and Shakow and obtained as striking results using the Set Index. They discuss alternative theories to account for the results, such as blocking, differences between fast and slow responders among the schizophrenics, and differences between normals and schizophrenics in the rate of build-up of reactive inhibition. No evidence was found in the data to support any of these alternative hypotheses. Hence, the findings of Shakow and his colleagues and their hypothesis to explain them remains a challenge which should stimulate much more investigation than it has so far done.

larger conditioned response than do strong stimuli) and "ultraparadoxical" effects (in which excitatory stimuli are converted into inhibitory ones and inhibitory stimuli into excitatory ones). Such stimuli are said to be of ultramarginal strength. According to Pavlov schizophrenic withdrawal and negativism are examples of paradoxical and ultraparadoxical phenomena. In two studies (1956*a*, 1956*b*) using different intensities of visual stimulus, Venables and Tizard did indeed find that chronic schizophrenics responded more quickly to weak stimuli than to strong.¹ In another study (1956*c*) they showed that on a repetitive task chronic schizophrenics fell away more quickly than did normals. These results are interpreted as due to the more rapid growth of reactive inhibition in schizophrenics. This hypothesis also helps to account for the recovery shown after rest, since this would be due to the dissipation of reactive inhibition.²

The results obtained by Venables and Tizard are striking and merit intensive further research in spite of the criticisms levelled earlier at the deficiencies of experimental control. However, it should be remembered that Tizard and Venables (1956) failed to obtain

¹ Compare the effects found with neurotics and normals above.

² The duration of the task is too short to enable normal subjects to develop significant amounts of reactive inhibition.

evidence that reactive inhibition had anything to do with the results obtained in the Rodnick-Shakow type of experiment;¹ that the differences they refer to may be a result of *basal* level of inhibition rather than differences in rate of growth of inhibition; and that, in view of Eysenck's work reported above (see also S. B. G., Eysenck, 1956), their differences may well be related to *psychoticism* rather than to schizophrenia *per se*.² Finally, attention should be drawn to the fact that Venables and Tizard (among others) have consistently obtained significant differences between acute and chronic schizophrenics and it is at least possible, therefore, that these differences are not related to the specific illness as such, but to an interaction effect between illness and length of stay in hospital.

It is clear from the above review that psychomotor tests have had a long and fruitful history in abnormal psychology. They have, however, proved to be of most value when used for testing specific hypotheses. In view of the recent tendency in this field for theory to assume a more significant role, there is no reason to doubt that they will prove even more useful in the future.

CHAPTER 3

Expressive Movements and Abnormal Behaviour

J. C. BRENGELMANN

INTRODUCTION

As reviewed in the present chapter, *expressive movement* deals with the relationship of individual differences of involuntary motor behaviour to personality and abnormality, whether occurring during spontaneous or purposeful movements.

Psychogenic or organic motor disturbance, or disorganization, is not dealt with. The effects of abnormality are discussed in so far as abnormals behave with regard to variables which are traditionally registered under "expressive movement" in normal personality. For that reason, the classification used disregards systems employed in psychiatry, whether of the observational or inferred, anatomical-neurophysiological or psychoanalytical kind.

Results discussed are based on experimental evidence. Originally, between World Wars I and II, most of the links connecting expressive movement with personality were not directly measured. The widely used methods of ratings and matching of rated characteristics are, because of a number of inadequacies, disappearing from the scientific stage. They consequently will be given much less space than in the past. Instead, some of the more recently developed methods, promising far more favourable prospects, are discussed in greater detail. This implies the opinion that research in expressive movement, having reached the end of a stimulating cul-de-sac with rating techniques, will flourish again under the guidance of objective measurement. Trends of this kind are indicated. But, as they are only trends, the relative emphasis in this report will be placed on methodology and measurement.

The formulation of a general theory of expressive movement appears premature. It would not furnish predictions of unique consequence, nor be capable of specifying the conditions under which certain modes of expressive movement occur. However, a number of limited suggestions with possibly wider applications and considered fruitful for the advancement of research, will result from the discussions.

In the present rather exploratory stage of the objective analysis of expressive movement classifications are bound to be tentative. Since Allport and Vernon's *Studies in Expressive Movement* (1933) no appreciable improvement in description, or factorial classification, appears to have been made. In the present review, the first section deals with various forms of gross motor expression. In the remaining three sections, for reasons indicated above, methods of assessments, or tests, have been treated in an order, not obligatory, of "objectivity" in assessment. The entire report is divided as follows --

I. Complex bodily expression

1. Gait
2. Gesture
3. Posture
4. Facial expression
5. Judgement of expression
6. Voice
7. Speech
8. Language

II. Complex products of arts and drawing

1. Artistic productions
2. Free drawing
3. Drawing completion
4. Evaluation

III. Semi-objective techniques

1. Copying of designs
2. Manipulative tests
 - (a) Mosaic Test
 - (b) Colour Pyramid Test
 - (c) Colour-star Test
 - (d) Bunch-of-grapes Test
 - (e) Evaluation
3. Handwriting

IV. Objective tests

1. Writing pressure
2. Prismatic tracing
3. "Kinaesthetic" drawing
 - (a) The Mira "myokinetic" test
 - (b) Simple blindfolded drawing
 - (c) Other movement tests
4. Figure Reconstruction Test

Finally, two more explanations are necessary. *Firstly*, certain aspects of expression, which are not of the motor type, have been discussed for reasons of completeness or immediate theoretical importance. *Secondly*, motor activities of the kind discussed in other chapters of the present volume have been dealt with when the reviewer felt satisfied about the usefulness of additions from the expressive movement point of view. Direct overlap in the content, it is hoped, has been avoided.

I. COMPLEX BODILY EXPRESSION

The subjects discussed under this heading vary to a considerable degree in the attention devoted to them; this appears largely to be a function of ease of measurement. Three points should be noted before discussing these subjects in detail; (a) although originally heavily favoured against other fields, research of the kind discussed in this section has become rare; (b) apparatus construction appears to have been in advance of research problems (objective measurement of complex movements, for example, has been described for decades without the implementation of corresponding personality research (Bernstein, 1927; Schleier, 1939; Voigt, 1939; Kretsinger, 1952); (c) where direct measurement of objective movement appeared difficult, as in the case of facial movement, traditional emphasis on "expression," or judgement of movement, has been retained. Although this has led to a distinction between the measurement of actual expressive movement and of individual differences regarding attitudes in judgement and perception, joint treatment still appears to be indicated.

Gait

Three papers of great originality have not been able to stimulate a systematic experimental investigation into personality characteristics of gait (Bogen and Lippmann, 1931; Wolff, 1935; Kietz, 1948). Objective methods of analysis have been known for decades but no publication relevant to the present subject can be quoted. (Anders, 1928; Schwartz and Vaeth, 1928; Liberson, 1936; Kreezer and Glanville, 1937; Glanville and Kreezer, 1937; Loucks, 1941.)

Gesture

Descriptions and classifications of gestures, supposedly expressive of personality rather than of cultural or conventional influences, have been frequently compiled (Allport and Vernon, 1933; Krout, 1935, 1954a, 1954b; Efron, 1941; Efron and Foley, 1947; Leonhard, 1949), but, pending experimental clarification, they are of little consequence. As long as there is no direct attack on personality correlates of gestures,

the vague belief will remain that most gestures are motor expressions of "feeling" and "emotion." A recent methodological improvement, however, may be recorded. Sainsbury (1954a, 1954b, 1955), extending Olson's (Young, 1947) method of time-sampling, used slow-motion film analysis of high reliability (split-half reliability of 0.93) to score nervous habits. Twelve patients were investigated under conditions of stressed and unstressed interviews, and gestural movements were found to increase with stress. Scores derived from the film sample correlated 0.998 with corresponding observational counting, and 0.87 with electromyographic scores. Emotionally disturbed patients, recommended for leucotomy, showed significantly more spontaneous nervous movements than did normal controls (1954a). This is consistent with other reports on increased gestural movement under stressful conditions (Jones, 1943a, 1943b).

The main merit of these studies appears to lie in the improvement of technique. The meaning of "stress" remains undefined and no differential effects between personality or abnormality criteria are known.

Posture

Psychiatrists and psychoanalysts alike have stressed that posture, as much as other gross bodily expressions, is characteristic of illness or unconscious psychological complexes (Deutsch, 1947). However, despite the fact that measurement of posture has shown individual differences to be both significant and reliable (Sollenberger, 1937; Travis, 1944; Allen, Taylor and Hall, 1945; Jones and Narva, 1955), the techniques developed have not been applied to measurement of personality and abnormality. A number of clinical observations on induced postural changes have been described but not systematically applied (Matthaei, 1924; Eidelberg, 1926). Schilder (Takala, 1953), for example, had his subjects stand with their eyes closed and their arms raised horizontally and extended sideways. It turned out that persons with neurotic tension tended unconsciously to let their arms come forward, while the tendency among the normals was rather the

opposite. Results relating to standing steadiness (Lee, 1931), or static ataxia, are reported in Chapter 2.

Facial Expression

Facial expression as the "principal focus of emotional expression" has assumed a "strategic position among the expressive agents of the body" (Allport, 1938). Despite this "one is confronted with the fact that the expressions of the human face have contributed least

movements of various face muscles in over two hundred patients. Schizophrenics, for example, were said to have "well differentiated" forehead muscles, but to find it difficult to "screw up" their eyes.

The fact that, in humans, the assessment of facial muscle movement has not been developed beyond a rudimentary level has resulted in an almost exclusive preference for dealing with "expression proper," i.e., that portion of perception which evokes immediate

FIG. 3.1. *Left:* SCHIZOPHRENICS RATE THEIR OWN EXPRESSIONS MORE FAVOURABLY DURING UNCONSCIOUS, BUT LESS FAVOURABLY DURING CONSCIOUS (C-E), EVALUATION

Right: DURING UNCONSCIOUS SELF-EVALUATION, JUDGEMENT BECOMES MORE FAVOURABLE WITH INCREASED RECOGNITION OF SIMILARITY WITH PERSONAL EXPRESSION

(From Epstein, 1955)

to the detection of practically useful points of view but most to the theory of expression effect" (Rohracher, 1948). One good reason for this is that the analysis of facial expression has been predominantly dependent on judgement, the unreliability and bias of which have been discussed a number of times (Allport, 1938; Vernon, 1953; Taft, 1955; Mühle, 1956; Gage, Leavitt and Stone, 1956).

Direct measurement of face muscle movement has, on occasion, been attempted (Lynn, 1940; Coleman, 1949), but has not progressed to the stage of assessing individual differences. From the point of view of measurement, Wörner's (1940) time sequence analysis of facial movements recorded from monkeys appears to be of outstanding importance.

In order to assess constitutional differences along Kretschmer's lines Oseretzky (1932) described the

emotional attitudes and judgements not present in, but attributed to, the stimuli (Rohracher, 1948). These are dealt with in the following section.

Judgement of Expression

Instead of dealing with expressed movement *per se*, we are now analysing a mixture of stimulus movement and the attitudes of the observer towards such movement.

This medium, though complex, holds out great promise for the study of personality, as Wolff (1933, 1943) has demonstrated on a number of occasions. Given suitable experimental conditions, subjects fail to recognize their own face, voice, hands, writing, gait, etc., but may react "unconsciously" to such exposures with emotions varying in intensity and quality. When subjects were asked to evaluate their

own unrecognized expressions, most of the judgements were found to be highly favourable, others were highly unfavourable and only a few were objective. These results were later confirmed by Huntley (1940).

Epstein (1955) in a most intriguing experiment investigated self-judgement of voice-backwards (V-B), handwriting-upside-down (H-U), voice-forwards (V-F), handwriting-right-side-up (H-R), names (N) and drawings (D) in normals and schizophrenics. The results are shown in Fig. 3.1.

This figure shows that self-evaluation is negative with highly disguised material. As the disguise decreases, self-judgements become increasingly favourable up to the point where complete identification occurs (i.e. drawings, or D), whereupon self-ratings become more modest. During *unconscious* evaluation, schizophrenics rated their own expressions significantly more favourably than did normals. In *conscious* evaluation (C-E), however, the opposite effect was found. Furthermore, Fig. 3.1 shows in a striking manner that during the period when subjects actually did not recognize expressions to be their own, favourable judgement increased with the degree of judged similarity with their own expression.

This experiment, although not strictly falling into the realm of expressive movement, has been reported because of its potential value in this field. In Sect. IV of this chapter it will be shown that confidence in performance, as one form of self-evaluation, interferes *directly* with objective expressive movement scores. Similarly to Epstein, the present author has found that such confidence depends on exposure conditions as well as defines certain personality correlates varying with such conditions.

Judgement of facial expression has led to yet another line of research. Eysenck (1954) reports an experiment in which normals, neurotics and psychotics were asked to judge various facial expressions from twelve photographs of male and female persons. Standard judgement check lists were used and deviation from a normal norm was scored, with the result shown in Fig. 3.2. High score signifies high agreement with the control norm.

Differences between the three groups were significant at the 0.1 per cent level and it may be seen from the above figure that deviation from the norm was highest for the psychotics. Essentially similar results were subsequently obtained by Chambers (1957), who used Szondi pictures as a basis for judgements. This author concluded that "as mental pathology increases in severity, conformity with the perceptual judgement of normals decreases."

The problem of variability in judgement of facial expression comes up again in the discussion of the Colour Pyramid Test (Sect. III). As this test is considerably different from the ones described above,

it may be suggested that the higher response variability in abnormals is of a fairly general kind.

This statement does not seem to add much to what is known already from other fields of personality research. However, there is a suggestion that judgement variability, as part of a more general response set, is of a heterogeneous nature. Eysenck, in his paper quoted above, states in a side remark that the judgements of neurotics were more *negative* and of

FIG. 3.2. AGREEMENT IN JUDGEMENT OF FACIAL EXPRESSION WITH A NORMAL STANDARD

This is high for normals and neurotics and low for psychotics
(From Eysenck, 1954)

psychotics more *positive* than those of normals. This is consistent with the present author's recently published results obtained by investigating response set by means of an adjective check list. It was found that schizophrenics, as against normals and neurotics, scored highest on *positive* extremes; neurotics, however, highest on *negative* extremes (Bregelmann, 1958e; 1959a). It is suggested that these results agree with the finding of Epstein, reported above, that schizophrenics judge their own expressions rather favourably. Judgement of expression, response variability, confidence in performance and extreme response set may then be considered part of a general factor of self-esteem, which would be highly dependent on experimental conditions for its manifestation.

Voice

Since Pear's (1931) pioneer experiments, a number of investigations involving ratings and matching have been performed. Sanford (1942), in his extensive review, has presented evidence to indicate that "mainly at the level of impression" voice does express personality. However, as with other complex media of expression, such as facial and artistic expression, the flourishing times of early impressionistic

studies have passed (compare other reviews: Rohrer 1948; Bell, 1951; Vernon, 1953). They have left us with the impression that voice appears an important means of studying individual differences in expression, without presenting any definite results. We are still left to rely on observational classifications such as those provided years ago by Newman and Mather

experiment (Table III.1) that, under stress, validity of intensity of voice may change. (These results are discussed further below.) Intensity correlated *positively* with "sensitiveness" and "emotional reticence," both of which can hardly be said to be typical of pyknic behaviour. Unfortunately, correlations for unstressed conditions were not given. At this point,

FIG. 3.3. LOUDNESS OF VOICE MEASURED BY THE DECIBEL RANGE

This increases in the order athletics—leptosomes—pyknics. Compare Fig. 3.11 for similar results on writing pressure.
(From Grunewald, 1957)

(1938) and Moses (1942), despite the fact that adequate equipment for phonometry (Murray and Tiffin, 1933; Zwirner, Maack and Bethge, 1955; Grunewald, 1957), and sound spectrography (Potter, Kopp and Green, 1947), etc., has been available for a long time.

Experimentally controlled work has been an exception. The frequently stated relationship between "melism" (Moses, 1942) and Kretschmer's somatotypes has been reaffirmed by Grunewald (1957), who found that pyknics manifested more melism than leptosomes and athletics. In addition, *loudness* of voice, as measured by its range, increased in the order athletics—leptosomes—pyknics (Fig. 3.3) similarly to writing pressure (Fig. 3.11). Both variables, it will be remembered, scored high loadings on Allport and Vernon's (1933) factor of emphasis. Grunewald's reference to the possibility of a factor of variability transcending various modes and media of expression receives some support. This, together with Allport and Vernon's suggestion of two independent types of variability, should be followed up.

In the light of Grunewald's results, the interesting suggestion may be derived from Korobow's (1955)

the pressing need for situational or conditional analysis may be underlined once again.

Speech

Although speech and language are not, strictly speaking, part of motor expression, their "emotional" aspects will be reported briefly so as to supplement the "cognitive" side discussed elsewhere in this volume. In a series of analyses, though on only a small number of subjects, Goldman-Eisler has investigated various basic conditions, some of which are referred to below. Certain relationships of time sequences of action and silence were found to be both characteristic of individuals and relatively constant (1951). While interviewers showed themselves consistent irrespective of the type of patient interviewed, they differentially modified patients' conversational activity (1952). In agreement with previous findings, speech rate was most consistent and sensitive in measuring differences between individuals (1954), as also was the rate of respiration and number of syllables spoken per respiration (1955).

Individual variations in speech activity are expected

clinically to correspond with fluctuations in tension and affect (Dollard and Mowrer, 1947; Kauffman and Raimy, 1949). Investigators have, accordingly, employed these conditions to analyse and vary such emotional states in a controlled manner. Korobow (1955), using three degrees of delayed auditory feedback as stress means, related a number of vocal elements to certain situational feelings and personality characteristics, as measured by questionnaires and check lists. Some results are shown in Table III.1. "Fracture" means stressing the individual syllables of words, i.e. ex'ten'u'a'ting, or stretching or slurring of words; "regression" the repetition of a word to correct either the whole word or a portion of it; "intrusion" the interpolation of ah's, eh's, um's, oh's, etc., between words and sentences.

TABLE III.1

* Significant at 0.05 level; all other correlations significant at 0.01 level

Results show that speech variables change significantly with stress and that stress effects are related to self descriptions of the "emotional" kind, whatever these may be. Similar types of speech disturbances in two patients were judged to be related to the degree of anxiety present during the interview (Mahl, 1956) without, however, a formal test of this assumption being conducted. Dibner (1956), analysing speech samples of thirty-nine patients, found two types of uncorrelated speech disturbance; one composed of indicators of speech disruption, the other of non-verbal reactions (sighing, laughter and voice change). These were considered indicators of situational anxiety,

aroused through the interview technique, rather than of a more permanent personality trait of anxiety, as measured by the G.S.R., ratings and self-reports.

Further experiments are bound to reveal relationships of greater complexity. Westrope (1953) and Benton, Hartman and Sarason (1955) have, for example, shown that the rate of verbal productivity in normals correlates positively with the Taylor Manifest Anxiety Scale which, in Eysenck's terminology (Franks, 1956), is known as a measure of neuroticism. On the other hand, although neurotics no doubt score higher on the M.A.S. than normals, their productivity appears to be considerably lower (Balken and Masserman, 1940; Lorenz and Cobb, 1953).

None of the experiments quoted in this section have been repeated. However, it appears safe to say that "emotional involvement" may be assessed by using diverse measures of speech activity and other peripheral signs accompanying speech. Experiments reveal the problem to be a complex one, requiring more experimental work before personality validation will offer lasting results.

Language

The use of language to measure expressive behaviour in psychiatric patients has been described a number of times in a systematic manner (Woods, 1938; Lorenz, 1952, 1955; Lorenz and Cobb, 1953). The main results of an experimental kind may be presented in three sections.

The *first section* deals with the *active/qualitative form of construction*, or the verb/adjective quotient (V.A.Q.) and the number of adjectives. The statistical analysis of these two scores is taken to have started with Busemann's (1925, 1926) finding in children that the V.A.Q. correlated positively, and "adjectives" negatively with ratings of "emotional instability." In other words, "activity" was indicative of instability and "qualitative" construction of stability.

Using responses to T.A.T. pictures, Balken and Masserman (1940) found that in neurotics, divided into conversion hysteria, anxiety and obsessive-compulsive states, hysterics used more adjectives and a smaller V.A.Q. than the other categories. Lorenz and Cobb (1953) found the V.A.Q. to be higher and "adjectives" to be lower in neurotics (all hysterics) than in normals. (Manics behaved similarly to neurotics.) Benton, Hartman and Sarason (1955), using normals, obtained a positive relationship between Taylor's Manifest Anxiety Scale, which is known to measure "neuroticism" (Franks, 1956), and the V.A.Q. The relationship to "adjectives" was negative, but acceptable significance was not reached in either case. Other results, consistent for spoken (Fairbanks, 1944) and written language (Mann, 1944), showed schizophrenics to vary similarly to other

abnormals. The results are presented jointly in Table III.2.

This table shows that the V.A.Q. is lowest, and the adjectives score highest, for the stable/hysteric/normal/low anxiety types of personality. Firstly, it may be assumed that "activity" of language increases and "qualitative use" decreases with abnormality and/or neurotic tendencies. (Anxiety and obsessive-compulsive states tend to higher scores on neuroticism

higher than hysterics. So far, results on the use of pronouns are similar to those obtained using the V.A.Q. and the "adjectives" score. It is as well, however, to keep in mind that the pronouns score varies with the interviewer (Goldman-Eisler, 1954b).

"Because of the schizophrenic's self-preoccupation and his tendency to ignore his environment," pronouns, and in particular self-referrals, should be more frequent than in a normal person (Fairbanks, 1944).

TABLE III.2
"ACTIVE" AND "QUALITATIVE" LANGUAGE CONSTRUCTION IN NORMALS AND ABNORMALS

Score	Verb-Adjective quotient		Adjectives†	
	High	Low	High	Low
Busemann* (1925) (normals)	unstable	stable	stable	unstable
Balken and Masserman* (1940)	anxiety states (3.11) (medium: obs.-comp. 2.17)	conversion hysterics (1.35) s.-comp. 2.17)	hysterics (medium: obs.-comp.)	anxiety states
Lorenz and Cobb (1953)	hysterics (1.70) manics (1.68)	normals (1.07)	normals (12.2)	hysterics (10.6) manics (9.6)
Benton, Hartman and Sarason (1955)† (normals).	high anxiety (5.13)	low anxiety (4.97)	low anxiety (3.55)	high anxiety (3.38)
Fairbanks (1944)	schizophrenics (4.90)	normals (3.43)	normals (6.69)	schizophrenics (5.37)
Mann† (1944)	schizophrenics (2.38)	normals (1.98)	normals (9.45)	schizophrenics (8.33)

* Significance unknown.

† Not significant.

V.A.Q. of Fairbanks and Mann computed from mean scores.

‡ Percentage of total word sample

questionnaires than hysterics.) Secondly, on account of Balken and Masserman's results, Eysenck (1950) has suggested that a "factor of dysthymia-hysteria" is involved. This aspect should also be explored.

Variations in score norms between investigators are considerable. As long as stimulus conditions are not standardized between groups, results cannot be assessed adequately.

In the *second section*, the *use of pronouns*, in which large individual differences have been found, is discussed (Conrad and Conrad, 1956). A high score is said to be associated with egocentric impulses or emphasis on communication. The incidence of the first person pronouns (for example, I, my, mine, me, myself) may mean rigidity in shifting from the subjective point of view; or a negative attitude to be disguised or dissimulated (Lorenz and Cobb, 1953); these authors found that abnormals, neurotics more than manics, had higher scores than normals. Within the neurotics, anxiety and obsessional-compulsive states scored

This was in fact confirmed, as far as spoken language is concerned. However, Mann (1944), using written language, obtained results of a contradictory kind. At the present time it appears difficult to say whether this is due to differences in the response mode (spoken versus written) or in the type of patient.

The *third section* of language characteristics deals with "*vocabulary inflexibility*." As it borders on the cognitive field rather closely it will be referred to only briefly. Johnson (1944), introducing a methodical and comprehensive study of language, devised the "type-token ratio" (T.T.R.). This is the ratio of the number of different words (types) to the total number of words (tokens) in a given passage. As might be expected, the mean T.T.R. of schizophrenics was significantly lower than that of normals in both spoken (Fairbanks, 1944) and written language (Mann, 1944). The latter author's results are shown in Fig. 3.4. It may be added that both authors accepted these results to be essentially independent of intelligence.

FIG. 3.4. CUMULATIVE FREQUENCY CURVES OF T.T.R.s FOR TWENTY-FOUR SCHIZOPHRENICS AND TWENTY-FOUR NORMALS

Means are shown by vertical lines. High T.T.R. means great "flexibility."

(From Mann, 1944)

A somewhat similar experiment was performed by Mittenecker (1951). This author scored interview material obtained from normals and schizophrenics for (a) number of *repetitions of syllables*, (b) number of *syllables repeated*, and (c) mean *distance between repetitions*. Schizophrenics scored higher for (a) and

(b) and lower for (c). A combination of all scores resulted in discrimination between the groups without overlap.

Results show consistently that the use of vocabulary is more "inflexible" in schizophrenics than in normals.

II. COMPLEX PRODUCTS OF ARTS AND DRAWING

Artistic Productions

Since Prinzhorn's (1919) monograph concerning *Das bildnerische Schaffen der Geisteskranken* interpretation of the artistic productions of mental patients has been extensive both in psychiatric and psycho-analytical work. Preference in treatment of such data goes to that derived from psychotics and the main conclusions reached were summarized by Mosse (1940) as follows: (1) the paintings of psychotics show a marked similarity to the drawings of children and of primitive peoples; (2) there are typical pathological signs such as stereotypy, mannerisms, symbolism, strange inaccessibility, etc.; (3) there is failure to

achieve anything like realistic representation. If these conclusions could be accepted as they stand, one could indeed speak of progress in this field.

Anastasi and Foley (1940) were also impressed by the great claims made. It appeared, however, that interpretations were inflated by uncontrolled speculation, particularly of a psychoanalytic kind, and that clear clinical pictures did not, as a rule, emerge from the study of artistic productions.

Some examples of drawing characteristics, claimed to be typical of abnormals, are given. The choice of small paper for drawing was related to neurotic depression and anxiety. Aggressive patients

preferred large paper. Unusual positions of drawings on a page were found in the work of depressives; *horror vacui*, or compulsive filling in of all spaces, in that of psychotics. Small drawing in relation to size of the paper was found in compulsion neurosis. Psychotics produced contaminating lines, overlapping functions of lines and criss-cross outlines of figures. Their drawings were also more repetitive and stereotyped. Some interpretations of lines may be quoted. Fuzzy and sloppy lines were taken to mean escape from rigidity, thin lines to mean repression, vertical lines greater assertiveness, circular lines greater submissiveness, spirals excitability, etc. Bell (1951) in his twenty-six-page summary table of drawing and painting characteristics provides these and hundreds of other alleged relationships.

Many of these appear quite reasonable. However, methods and interpretations vary so much between authors that an attempt to assess the consistency of the results must remain both frustrating and fruitless. More experimentally-minded authors, employing art productions mainly in the assessment of personality and adjustment, attempted a certain amount of standardization in procedure. The method generally used is demonstrated in the following three studies of personality, which are usually taken to be some of the best controlled ones in this field (compare the review by Precker, 1950).

Paula Elksch (1945) selected the productions of eight children from a collection of 2,200 paintings and drawings made by a great number of children. They were rated for the following criteria of style: complexity-simplicity, expansion-compression, integration-disintegration and realism-symbolism. These criteria were related to sociometric ratings of "adjustment." These were as heterogeneous as were the art productions, and high correspondence was obtained.

Using the work of fifty-five freshmen or sophomore girls, Waehner (1946) drew up personality sketches from a series of "free" drawings, mainly from formal elements like size, format, distribution of form-elements, quality of lines, organization of form, perspective, shading, etc. Teachers then matched Rorschach interpretations with these sketches and correct matching is claimed in 87 per cent of the cases. The subjects were investigated in small groups of five to six.

In an extensive study of self-portraits, drawn by forty boys and forty girls, Stewart (1955) analysed thirty-one rated variables such as realism, skill, symmetry, qualities of line, etc. After factor analysis, the six clusters found were correlated with personal inventory scores, behaviour ratings, and ratings of inferred needs. Results which were of interest showed "skill quality" to be related to maladjustment and neurotic introversion in the boys' sample, but to

creativity and "adjustive introversion tendencies" in the girls'. Width and variability of line correlated with "dominant extraversion" for the boys and with sociability and adjustment for the girls.

These three examples, selected for their outstanding quality, are in many ways typical of a great number of related studies in so far as they reveal a number of methodological weaknesses. Of these, only the most fundamental ones will be mentioned at present. It may be said, firstly, that criteria of art productions, whether of an impressionistic or analytic kind, and corresponding ratings, or other assessments, of personality have been largely *specific to investigators*. This makes comparison between investigators and, therefore, recognition of general trends in expressive behaviour difficult. The conclusion usually is that a certain investigator has made certain observations, the validity of which is restricted to that particular study.

A second criticism is directed against the *matching method*, predominantly used in studies discussed in the present section. It is now widely agreed that this method served as a "stop gap with little future," its main drawback being the impossibility of saying which of the numerous aspects of a personality sketch, a psychogram, or a case-study as a whole are the significant ones. Wrongly applied this method is also widely open to *contamination*. In most cases raters knew both the art productions and the subjects involved. They may, therefore, in their assessment have been influenced by extraneous cues. This would explain the numerous claims of positive results, which shrank to an insignificant degree when more rigorous methods of assessment were applied, as will be seen later on.

Free Drawing

Growing out of the assessment of artistic production a number of drawing techniques have been developed with varying limitations of instruction. This modification may be appreciated as one step towards standardization of procedure. Of the many techniques proposed, those which have received very little attention are not considered. Some of these are: the "Projective-Motor Test" (Rapkin and Wheeler, 1949); the "Most-Unpleasant-Concept Test" (Harrower, 1950); the "Family-Drawing Test" (Hulse, 1951); the "Baum Test" (Koch, 1951); the "Eight-Card-Redrawing Test" (Caligor, 1952); the "Rosenberg Draw-a-Person Test" (Levy, 1950); the "Inside-of-the-Body Test" (Tait and Ascher, 1955); the "Animal-Drawing Test" (Schwartz and Rosenberg, 1955); and the "Draw-as-an-idiot-would Test" (Ponzo, 1957).

Of the techniques classifiable under this heading, the "Draw-a-Person Test" (D.A.P., Fig. 3.5), derived from Goodenough (1926) and Machover (1949) has received greatest attention. It is discussed, here,

jointly with Buck's (1948*a*, 1948*b*) "House-Tree-Person Test" (H.T.P., Fig. 3.5). Projective psychologists claim that results obtained by this technique are indicators of abnormal behaviour, as follows: "These psychomotor expressive productions reveal all components in the personality that revolve around the body-image, for example, acceptance of sexual role, anxiety or depressiveness in the sphere of interpersonal relations, anxiety relating to bodily processes or structures, relative degree of rigidity or flexibility of the personality, tendency to withdraw from reality, low sense of self-esteem or inferiority complex, etc." (Abt and Bellak, *Projective Psychology*, pp. 441-2, 1950). This is only a small portion of the great number of claims made by various projective psychologists. It may be all the more surprising to read in the same volume of *Projective Psychology* the following statement by Levy (1950): "In order to avert cynicism and disillusion it is well to emphasize that the technique of analysing drawings is without experimental validation, rarely yields unequivocal information, and frequently misleads the unwary into plausible mis-statements about the personality of the person whose drawings are being studied."

When the evidence obtained has been examined, correlations with abnormal criteria have provided the following results.

It may be seen from this table that significant differences between normals and abnormals were obtained in every instance, but not between the various groups of abnormals. This statement, however, is not to be interpreted as a definite conclusion for at least three reasons. As a rule, the effect of interrelated scoring items was not analysed, cross-validation was not carried out and in most instances tester and scorer were identical, thus exposing scoring to contamination. Each one of these criticisms would suggest invalidity for almost the entire result.

This has in fact been demonstrated by more rigorously controlled studies. Having investigated human figure drawings by one hundred controls (dental patients) and eighty anxiety neurotics, Royal (1949) found that eight out of twenty-eight items tended to differentiate between the two groups. However, these eight items did not hold up under cross-validation. Similar results of cross-validation were reported by Michal-Smith (1953) and Kotkov and Goodman (1953). After matching controls (thirty-nine veterans awaiting dental treatment) and schizophrenics ($N = 39$) for age and school grades, Stonesifer (1949) obtained no significant differences between the groups, using the Goodenough point score. Having correlated human figure drawing scores with eight carefully prepared personality ratings of reasonable reliability (median of 0.82), Zimmer (1955) found very low coefficients (median of 0.16). In a

carefully designed study, Whitmyre (1953) found that adjustment, as rated from drawings of the human figure, did not discriminate between fifty psychiatric patients and fifty normals.

Successful results have been claimed in investigating the prognostic value of drawing techniques, similarly

FIG. 3.5. EXAMPLES OF RESPONSES TO THE DRAW-A-PERSON AND HOUSE-TREE-PERSON TESTS

to validation against abnormal criteria (Fiedler and Siegel, 1949; Ochs, 1950; Cowden *et al.*, 1955). These studies are open to the criticisms already made. Again, applying cross-validation to the psychiatric selection of flying personnel, Anastasi and Foley (1952) found considerable shrinkage in a number of significantly differentiating items, although a modest degree of success was retained. Certainly, more work is required to form a final judgement.

A third type of "validation," concerning the "content" of drawing expression, is mentioned only briefly. The analysis of "psychosexual adjustment" is taken as the outstanding example ever since

Machover's first reinterpretation, in terms of sexual adjustment, of the Goodenough intelligence test. In the H.T.P., for instance, some investigators insist that a tree or a chimney pot looks "phallic" and serves as an indicator of "psychosexual conflict" (Jolles, 1952*a*, 1952*b*). Sloan (1954) has already furnished reasonable

ratings of personality characteristics to D.A.P. scores, has already been mentioned as not successful.

On the surface, more promising results have been obtained by Witkin *et al.* (1954). Four graphic features: lack of body confidence, absence of struggle for sexual identity, lack of drive and a total drawing

TABLE III.3
PSEUDO-POSITIVE RESULTS AS AN EFFECT OF FAILURE TO CONSIDER ITEM-INTERCORRELATION,
CROSS-VALIDATION AND CONTAMINATION

Author	Test	Subjects	Results
Anastasi and Foley (1944)	D.A.P.	340 C., 340 abnormals	61 per cent of 23 items differentiated at the 1 per cent level
Albee and Hamlin (1950)	D.A.P.	30 C., 21 anxiety neur., 21 schiz	Pooled ratings. C-neur. (1 per cent); C-schiz. (1 per cent); Neur.-schiz. (N.S.)
Goldworth (Abstract 1950)	D.A.P.	50 C., 50 neur., 50 schiz., 50 brain damage	13 per cent sign. differences of 306 comparisons between 4 groups
Holzberg and Wexler (1950)	D.A.P.	78 C., 38 schiz., (of these: 18 paran., 12 hebephre., 6 cat.)	13 per cent of 174 items differentiated at 5 per cent level between C and abnormals. No sign. differences between abnormals
Singer (Abstract 1950)	H.T.P.	40 C., 34 schiz.	28 per cent of 428 items differentiated at the 5 per cent level
Eigenbrode (Abstract 1951)	D.A.P.	40 C., 40 schiz.	14 per cent of 184 items differentiated at the 5 per cent level
Gerard and Kornetsky (1955)	D.A.P.	23 C., 33 opiate addicts	Maturational level (N.S.). Rigidity (1 per cent). Conventionality score (2 per cent)
Reznikoff and Tomblen (1956)	D.A.P.	25 neur., 25 schiz	18 items. Neur. v. schiz. (N.S.)

D.A.P. = Draw-a-Person

H.T.P. = House-Tree-Person.

C = normal controls.

Neur = neurotics.

Schiz = schizophrenics.

criticism of such vague concepts which are "operationally indefinable" and "therefore intrinsically invalid symbols." As for the D.A.P., a competent review of the literature by Brown and Tolor (1957) has shown that "there is no convincing evidence that adequacy of psychosexual identification or adjustment is reflected in the choice of sex" and that "homosexuals do not draw a figure of the opposite sex first, contrary to widespread hypothesis."

This "muddled picture of the validity of human figure drawings" as Zimmer (1956) sees it, requires "experiments designed to yield definite answers." Steps have been taken in two directions. Drawings have been related to more objective criteria and the interference of some irrelevant factors has been defined. Zimmer's (1955) study, relating reliable

score were derived from the D.A.P. and yielded nearly consistently correlations significant at the 1 per cent level (in both males and females) with perceptual tests. Some kind of cross-validation is said to have taken place. These results may be regarded as encouraging in themselves. However, they in no way validate the postulated relationship between "field-dependent" performance and the "counterparts of personality characteristics" (D.A.P. scores), quoted above. Terms like "body confidence," "struggle for sexual identity" and "lack of drive" are meaningless until they are validated and operationally defined. In addition, as "personality" scores, they are much too complex to be used as dimensional measures and have no unitary meaning (Gruen, 1957).

One major source of error in making interpretations

has been uncovered. According to Goodenough's original intention, the D.A.P. was intended to serve as a measure of intelligence. Although results have remained inconclusive for reasons of unreliability in D.A.P. scoring, widely varying scoring items and types of subjects used, significant correlations between figure drawing, as well as H.T.P., and various types of intelligence tests have repeatedly been obtained (Buck, 1948*b*; Ansbacher, 1952; Murphy, 1956). This fact should compel investigators wishing to make personality inferences to assess and consider the role of intelligence. This has rarely been done and may in part have been favourable to the appearance of pseudo-successful results in relation to drawing techniques.

A further, and perhaps more important, source of error in making interpretations is interindividual variation in drawing proficiency, or artistic excellence. Albee and Hamlin (1949) indicated that the quality of the drawing may influence interpretation. Words and Cook (1954) produced evidence that placement of the hands in drawn representations of the human figure is a function of level of proficiency in drawing. The most important of all the papers quoted concerning drawing techniques is that of Whitmyre (1953). In a well-controlled study, this author asked twelve experts to rank the D.A.P. productions of fifty normals and fifty abnormals for degree of personal adjustment and artistic excellence. Further ranking for artistic quality was done by eight commercial artists. It was found that assessments for adjustment and artistic performance intercorrelated higher than 0.8 (*sic*). However, neither art nor adjustment ratings, made by psychologists and artists, were significantly related to the normal-patient dichotomy.

Drawing Completion

Of the various types of this test (compare the "Horn-Hellersberg Test," Hellersberg, 1945; Ames and Hellersberg, 1949; Frank and Rosen, 1949), only the "Wartegg Zeichentest (W.Z.T.)" (1939), predominantly used as a projective technique, has received sufficient attention to merit discussion. A theoretical system derived from the Leipzig Ganzheitspsychologie (Krüger-Sander) and including the following four basic functions, each accompanied by two more or less opposed characteristics, is used as a basis of interpretation (English version by Kinget, 1952)—

Wartegg Personality Functions (Fig. 3.6)

Emotion	(outgoing—seclusive)
Imagination	(combining—creative)
Intellect	(practical—speculative)
Activity	(dynamic—controlled)

A great number of formal and expressive response

categories are rated and represented configurationally, separately for the functions postulated (Fig. 3.6). In Germany, the W.Z.T. is extensively used by clinical psychologists both in normal and abnormal psychology, but validation apart from clinical impressions has not taken place. Where clinical groups have been used experimental controls are absent (Seiffert, 1951; Pfeiffer, 1951; Müller-Suur, 1952; Bauer, 1952; Luza, 1954).

It has, however, been found that Wartegg scores correlated significantly (0.79) with the Wechsler Scales (Anonymous, 1954; Stark, 1954), similarly to the drawing techniques described in the preceding section, and that primarily the W.Z.T. measures drawing ability and not personality (Mader, 1952). Both drawing skill and intelligence were found to interfere strongly with symptomatic traits (Takala and Hakkarainen, 1953). Intercorrelations of thirty-one scoring items with a variety of variables derived from personality questionnaires, interest inventories and ratings of situational behaviour and occupational success, yielded meagre results. A constructive proposition was, however, made by developing a multiple choice version of the W.Z.T., which would exclude the effect of drawing skill.

In a separate study by Takala (1953), only three of one hundred and fifty-four correlations between the W.Z.T. and a variety of questionnaire, psychomotor, expressive movement and projective technique scores were significant at the 5 per cent level (*sic*). It may safely be concluded that, at the present stage, personality and abnormality correlates of formal drawing characteristics of this kind are not known. Lossen's (1955) claim that "sequence analysis," instead of analysis of isolated items or drawings as a whole, measures "personality dynamics" and not traits cannot be accepted until proof is obtained. Sequence analysis, though logically a sound proposition, may merely reflect unspecific practice effects or unreliability.

Evaluation of Results

One may be in accord with the unanimous judgement of authors that artistic products and free drawing reveal very different aspects of personality and abnormality. This statement, however, is scientifically meaningless until we have demonstrated, *firstly*, that expressive movement *per se* is diagnostic of personality, and not via intelligence, artistic excellence, age, etc. *Secondly*, the basic measures of expressive movement, their functional conditions and personality correlates have to be defined in order to map out the field. The inescapable conclusion, after perusal of the literature, is that not one of these basic aims has even been approached during decades of analysis by some hundreds of investigators.

FIG. 3.6. RESPONSE AND EVALUATION OF THE WARTEGG DRAWING COMPLETION TEST
(From Kinget, 1952)

Before beginning detailed criticism, let us state the evidence agreed on between authors. Several reviews have already been quoted. Writers usually agree that *smallness and constriction* are expressive of neurotic signs of depression, anxiety and compulsion; of feelings of inferiority and timidity; of rejection and deprivation; of introversion and emotional dependence. *Large size and expansion* are taken to indicate outgoing, extraverted, aggressive and impulsive personalities. There is a back-door provided for observations which do not fit. "Over-controlled" persons, for instance, draw small or constricted, even when they don't fit the description given above. *Stereotyped rigid, repetitive and symmetrical arrangements* are claimed for a variety of categories like neurotic depression; maladjustment; self-centred, emotionally reacting and blocking personalities; paranoia; schizophrenia; psychotics in general and mental retardation.

There are some suggestions that *response variability* may be high in psychotics; *disregard of conditions* frequent with uncontrolled, asocial behaviour; *tendency to fill in* pronounced in schizophrenics and immature, aggressive, non-adaptive patients; consideration for *great detail* distinct in over- neat and pedantic personalities, and often in depressives; *odd responses* and *untidiness* more frequent in psychotics and feeble-minded; *sharp-edged versus smooth-curve lines* more frequent in overtly aggressive persons with low adjustment and *good proportion* to be more prevalent in persons with initiative and a good measure of social adaptation.

Few clinicians, on the face value of these claims, would challenge their appropriateness. However, a *summary criticism* of these and other claims, some of which have already been indicated, should convince the reader of the actual poverty and lack of stringency in the conclusions. The following points are made—

1. Any investigator knows that odd, extreme, and poor responses are predominantly found in untestable, deteriorated, feeble-minded or brain-damaged persons. These most impressive characteristics are usually not found in testable functional abnormals, equated for intelligence, age and absence of brain damage with normals. If *deterioration* and *co-operation* is accounted for, a large proportion of otherwise discriminating characteristics remains useless.

2. Investigators have, with little effect, already been frequently criticized for insufficient or inappropriate *application of controls*, inadequacy of sampling, contamination, interference of irrelevant factors, and lack of formal testing of validity and reliability. The last has been found to be strongly influenced by artistic aspects of performance, rather than by actual movement characteristics.

3. There has been a great lack of empirical investiga-

tion and examination of testable hypotheses. *Loose theorizing* and interpretations of the analytical kind such as "psychosexual problems were freely projected," "broad spotting indicated regression to anal stage," "attempted to overcompensate with extra-large reinforced feet," or of the expressive kind such as: "rigid quality of lines," "intellectual realism of painting," "free floating anxiety" in curves, wobbly lines of "low security," high pressure as "vitality," jittery lines suggestive of "imitation," etc., have remained dominating but useless. There is complete absence of experimental justification for such pseudo-scientific terms, techniques being used as "maids-of-all-work."

4. *Clinical criteria* such as neurosis, psychosis, conduct disturbance and maladjustment have been accepted as ready-made psychiatric concepts without any further refinement. These criteria are bound to be heterogeneous. The suggestion, perhaps the most convincing, provided by the literature that depressed, anxious and compulsive neurotics draw smaller and more constricted than the outgoing, contact-seeking and aggressive personality has never been followed up by constructing corresponding objective criteria in an attempt to test the alleged relationships.

5. *Scores* used were too complex, or varied profoundly in number and nature between the investigators. There has been no systematic item analysis between studies reported, nor was the effect of intercorrelated items assessed. This has resulted in a continued absence of meaning in the measures used.

6. Safeguarding *spontaneity of expression*, which is often invoked to defend neglect of experimental control and standardization, may well be an important point. It may, however, be argued that spontaneity would better be investigated by using *suitable* experimental controls to define its meaning instead of accepting any haphazard and incidental movements as scores. Subjects could be made to respond freely, visually as in the multiple choice proposition for the drawing completion test by Takala and Hakkarainen (1953), or else by manipulation, to all desired response types without artistic competence or intelligence interfering to a significant degree.

7. The *necessity of more objective scoring* procedures is shown by the high degree of error made in rating drawings. The agreement between various psychologists in rating such characteristics as paranoid signs, facial expression and stance was so low as to "suggest that it is precarious to accept most of the current assumptions regarding figure drawing analysis" (Fisher and Fisher, 1950). Moreover, experts agreed no more than untrained raters. Similarly, Blum (1954) exposed the "highly questionable validity" of the D.A.P. ratings from a number of other points of view.

III. SEMI-OBJECTIVE TECHNIQUES

Copying of Designs

Tests of copying and reproduction of designs have been used by Binet, Hetzer, Gesell and Kern, Rupp, Busemann, Ellis and Wolff (Wewetzer, 1956; Bell, 1951). The test of particular consequence for the

"good gestalt," etc. (Woltmann, 1950). These theoretical aspects, however, may be omitted from discussion as deviations in reproductions are so multivarious as not to follow the hypothesized gestalt laws.

The theory connected with the B.G.T., as expressed

FIG. 3.7. FORMS OF THE BENDER VISUAL MOTOR GESTALT TEST

present discussion is the Bender-Gestalt Test, for short B.G.T. (original monograph, Bender, 1938; manual of instructions, 1946, 1949). This test consists of nine simple designs each of which is presented to a subject to copy on a sheet of paper (Fig. 3.7). Designs stem from Wertheimer and are supposed to embody principles of "gestalt" like "proximity," "continuity,"

by Pascal and Suttell (1951), is either too general or lacking in precise definition to be of great use, but may be mentioned because of its historical interest and reads as follows. "The greater the damage to the cortex through convulsive therapy, amentia, lack of maturation, trauma, etc., the greater the deviations from the stimulus. . . . Deviations in individuals

without demonstrable brain damage reflect the individual's attitude toward reality. This attitude we believe to be a function of the integrative capacity of the organism, the ego."

As with free drawing, the B.G.T. has been used to assess a variety of things: maturation, intelligence, psychological disturbances, clinical improvement, age regression, brain damage and various kinds of physical treatments. Following the qualitative and interpretative phase of Bender, Hutt (1945), and others, more carefully controlled studies have been made as shown in Table III.4. In this context only the copying part of the B.G.T. is discussed, as drawing characteristics derived from the recall technique are known to be interfered with by memory. This would make separate assessment of "visuomotor" activity impossible, as movement and error aspects of the B.G.T. are difficult to separate. Results may now be inspected in the table below.

Because of repeated criticism, considerable efforts to improve objective scoring of the B.G.T. have been

made. The results, however, have been contradictory from the beginning. Of the six studies accepting Pascal and Suttell's scoring system (5, 6, 8, 9, 10, 11 of Table III.4), two showed negative results. These were decidedly the better controlled studies, as Gobetz cross-validated his findings and Tamkin controlled for age, which was shown to be significantly related to the B.G.T. In general, the conclusion may be drawn that this test did not differentiate consistently between normals and abnormals, certainly not between neurotics and psychotics, regardless of scoring procedure.

Although the B.G.T. was not shown to be consistently correlated with functional abnormality it may nevertheless predict clinical improvement. Swenson and Pascal (1953) claimed correspondingly that those patients who subsequently recovered had a significantly lower mean z-score on the B.G.T. at the time of admission than those who did not recover. Unfortunately, none of the possibly important characteristics of the improved-unimproved dichotomy like type of

TABLE III.4
RESULTS USING THE BENDER GESTALT TEST
Differentiation between normals and abnormals has remained inconsistent. The test does not differentiate between abnormal categories

Author	Groups tested	Results
1. Billingslea (1948)	50 C., 100 neur.	63 indices, 25 test factors, results essentially negative
2. Pascal and Suttell (1951)	474 C., 187 neur., 136 psych.	Sign. differences between C and abnormals, not between neur. and psych. 102 items
3. Hanvik (1951)	14 patients with organic and 23 with functional back complaints (neur.)	No sign. differences using 3 scoring methods
4. Suttell and Pascal (1952)	278 C., 117 neur., 54 schiz.	4 of 12 items at 1 per cent level between C and schiz., none between neur. and schiz.
5. Addington (1952)	43 C., 32 schiz.	P and S score sign. differences
6. Gobetz (1953)	285 C., 108 neur., cross-validation 54 C., 64 poorly adjusted	Failure of previous scoring systems. New system of 30 signs: sign. differences
7. Curnutt (1953)	25 C., 25 alcoholics	Sign. difference
8. Lonskin (1954)	37 neur., 36 psych.	P and S score, sign. differences
9. Bowland and Deabler (1956)	20 of each: C., neur., schiz., org.	P and S score between group sign., neur.-schiz. = N.S.
10. Sonder (1955)	40 C. with "normal" M.M.P.I. scores; 42 abnormals, mainly schiz.	P and S score, sign. difference
11. Tamkin (1957)	27 neur., 27 psych., age controlled	Neur. higher score than psych. (N.S.) No sign. correl. with M.M.P.I. scales

Schiz. = schizophrenics.

C. = normal controls.
Psych. = psychotics.

Neur. = neurotics.
M.M.P.I. = Minnesota Multiphasic Personality Inventory.

patients, chronicity, age and intelligence was stated. It is, therefore, impossible to say for what reason the subgroups differed. In addition, a correlation between *improvement* scores on the B.G.T. and in the clinical status might well have contradicted the conclusion, as improvement from error tends to be positively correlated with initial error level.

In a much better controlled experiment by Cowden, Deabler and Feamster (1955), two applications of the B.G.T. did not predict improvement consistently. At the same time, large discrepancies occurred between three other drawing tests (H.T.P., Self-Concept Drawing and Opposite-Sex Drawing). It may be considered a major fault in the design that functional and organic cases were mixed up apparently without any attempt to equate experimental and control groups for diagnostic label, nor any other important variable.

Sonder's (1955) outstanding experiment deserves greater attention and repetition with larger samples. This author, guided by indications from the literature, predicted that acute patients with good scores and chronic patients with poor scores will improve more than their opposites. Five tests, including the B.G.T., were administered within five days of admission to hospital. Patients admitted for the first time were classified as acute and those with previous admissions as chronic cases. Initial test results were then correlated with an independent psychiatrist's judgement of improvement at the end of a ninety-day period of hospitalization. The prediction was confirmed for both acute (6 per cent level) and chronic (1 per cent level) cases.

The results of these three studies are as heterogeneous as they can be, but provocative enough to call for validation under improved conditions.

An interesting attempt to test the psychoanalytic "regression" theory was made by Suttell and Pascal (1952). Fifty-four of each, schizophrenics, neurotics, adult normals and children of 6 to 9½ and 10 to 14 years of age, were tested. Those signs which differentiated between the two groups of children did not differentiate between adult controls and schizophrenics. The authors concluded that regression, as measured by the B.G.T., is not peculiar to the schizophrenic.

Evaluating the experiments quoted, it may be said that some progress has been made when compared with free drawing technique. Scoring systems and number of items scored have varied less excessively. Administration and scoring has become more standardized and objectified, and has been followed by a considerable increase in reliability.

Scoring, however, is by no means objective and remains unnecessarily complicated. As was stated in the beginning, deviations do not follow the gestalt laws supposed to be underlying the various stimuli.

They are, in fact, rather specific to stimuli and subjects, with the result that distortions are numerous. A *parallel test* to the B.G.T. does not exist and is, in fact, extremely difficult to construct. If the same test is given twice, learning from greater familiarity may take place resulting in poor discrimination (Gobetz, 1953).

The *psychological nature* of the B.G. score is too complex, and inextricably lumps together heterogeneous movement characteristics or distortions (compare F.R.T., Sect. IV). To mention only one example, the reduction to one raw- or z-score does not permit differentiation between movement and error. This alone would explain lack of consistent differentiation between abnormal criteria.

The *choice of criteria* has not progressed beyond the traditional categories of neurotics, psychotics, or maladjusted. With the exception of Murray and Roberts (1956), who investigated expansion-constriction of one patient during his manic and depressed phases, no suggestion as to any functional properties or more specific validity has been made. Neurotics have never been split up into subcategories despite their divergences in movement, as was suggested by clinical description, assessments of drawings and art productions, as well as from objective expressive movement tests. Lonstein's (1954) neurotics, for example, consisted mainly of anxiety states, which explains his significant differences obtained between neurotics and psychotics, as differences in expressive movement are greatest between dysthymics and psychotics (compare F.R.T., Sect. IV).

Finally, individual differences of *skill in assessment* of drawings affect the B.G.T., as much as other drawing techniques. Mehلمان and Vatovec (1956) submitted twenty-five paired protocols of organic and functional psychotics to three expert judges for "blind analysis." There were considerable differences between the judges, suggesting "a surprising heterogeneity of skill in the use of the B.G.T."

Manipulative Tests

The four tests described in this section have common elements in that they are primarily colour-reaction tests with the analysis of formal characteristics added, and that patterns are formed by manipulating a variety of stimulus items offered. The colour portion of the tests is largely associated with certain expectations of emotional reactivity. No particular *a priori* theory appears to have been set up for the structural, or formal portion. However, originators of the tests state, in general, that degree of abnormality correlates positively with poor structure.

MOSAIC TEST (LÖWENFELD, 1949, 1954)

This test consists of two hundred and twenty-eight (small box), or four hundred and fifty-six (large box)

standardized pieces of geometrical shapes, which may be of wood or other materials (Fig. 3.8). The small box contains twenty-four squares, forty-eight diamonds, forty-eight right-angled triangles, thirty-six equilateral triangles and seventy-two scalene triangles. The shapes are in six colours: black, white, red, green, blue, and yellow. The subject is asked to construct something on a wooden tray 13 in. \times 10½ in. and the resulting patterns are recorded.

Lowenfeld felt that the type of pattern made, apart from the choice of colour, was indicative of the "personality structure." She also found certain patterns or elements to be related to various clinical categories. Many studies, claiming the usefulness of the Mosaic Test in the abnormal field, were descriptive or simply classified responses (Wertham and Golden, 1941; Diamond and Schmale, 1944; Wertham, 1950; Johnson, 1957). Reiman (1950) gave the test to controls and patients with "habit disturbance," "conduct disturbance" and "neurotic traits." Although the significance of the results was not computed, it appears from the data supplied that only very few of the thirty-three items would discriminate significantly. "Scatter," for example, would be greatest in subjects with conduct disturbance and productions would be largest from subjects with neurotic traits. These findings were not cross-validated, but resemble those found with free drawing.

The frequency with which certain types of designs occurred was determined by Kerr (1939) in a sample of over one thousand subjects. Using selected subjects, she obtained fairly high correlations between mosaic pattern interpretation and diagnosis. The results may, however, have been affected by contamination, as the interpretations were made by the experimenter giving the test. This, and other criticism made by Himmelweit and Eysenck (1944-6), throws doubt on the validity of the results. The latter authors, in a carefully designed matching experiment, confirmed however that experts could match mosaics and personality sketches and could write personality sketches from mosaics, which were made by doctors, with better-than-chance success. The experts failed, however, in giving significantly correct judgements on a personality questionnaire completed by the patients. The most important results are judged to be those obtained by the layout of test elements. Dysthymics (obsessionals, anxiety states and reactive depressives) tended to produce compact designs, while hysterics tended to produce scattered and intermediate designs. The results were not cross-validated.

In Levin's (1956) well-controlled and comprehensive study, a great number of mosaic scores, derived from the literature, were analysed for differentiation between (a) institutional and non-institutional groups, (b) normals and abnormals (fifty-two normals, four-

teen "maladjusted," fourteen neurotic, thirty-four defective, twenty-nine parietic, and thirty-five schizophrenic subjects), (c) six diagnostic groups, and (d) between subjects with high and low scores on the clusters obtained from the Wittenborn Psychiatric Rating Scales. There is little need for further discussion, as the results were "sweepingly negative." The author suggests "that the discrepancies between clinical impressions and experimental findings may be

FIG. 3.8 THE FIVE SHAPES OF THE LOWENFELD MOSAIC TEST

Number of shapes used is stated in brackets.

attributed to failure to recognize that diagnostic cues are obtained from interview aspects of the testing situation, rather than from the Mosaic Test itself."

COLOUR PYRAMID TEST (FARBPYRAMIDENTEST, HEISS AND HILTMANN, 1951)

Stimulated by the Swiss psychologist Pfister (1950), this test has been developed and rapidly expanded in the Freiburg (Germany) Department of Heiss. A pyramid consisting of fifteen squares of 2.5 cm side length (Fig. 3.9) is presented to the subject, together with square bits of paper in twenty-four colours (four shades each of red, blue, green, three of purple, two of yellow, orange and brown and, finally, one each of black, grey and white). The subject is instructed to choose from these colours and to complete a pyramid. Usually three such pyramids are requested in one session. More recently the instruction to make "ugly" pyramids has been added (Heiss, Hornsberg and Karl, 1955).

The far-reaching claims of this technique and its extensive use in clinical work have been swiftly followed by fundamental criticism (Luthe and Salman, 1953) and by experimental test. From the expressive movement point of view, a number of formal characteristics in pattern construction like "carpets" (unstructured layouts), arrangement in "layers" and "structures" have been studied. Another classification divides responses into "orderly" and "disorderly"

arrangements. In the absence of statistical assessment, tests of significance were computed by the author where indicated.

Using neurotics, depressives, schizophrenics and controls Brengelmann (1953b), obtained no significant results, although means were in the predicted direction, indicating that abnormals, in particular schizophrenics, use fewer "structures" and construct in a more disorderly fashion. The effect of intelligence,

FIG. 3.9. STIMULUS FRAME OF THE COLOUR-PYRAMID TEST

age and sex was assessed. Frohoff (1953) reported highly significant differences between normals and controls, using norms published by Heiss as control data. Because he was not using his own controls, these data are not interpreted. When significance was assessed by the present author, no significant differences were found in Frohoff's data between four groups of schizophrenics (uncharacteristic, paranoic, hebephrenic and catatonic). The results were recomputed. In Seyfried's (1957) study, differences between seventy maladjusted boys and forty-five control subjects were significant at the two per cent level for both structuring (Chi-square of 9.099, 2 d.f.) and orderliness (Chi-square of 9.183, 2 d.f., results recomputed). Out of two hundred normals, Karl (1953) chose two groups characteristic of "strong" and "weak motivation" (Antriebsstruktur), using the upper and lower quartiles of responses to the Pauli Test (continuous arithmetic calculation). No significant differences in structuring were obtained (Chi-square of 1.636, 2 d.f., results recomputed). Conrad and Juncker (1954) first formed two extreme

groups of leptosomes and pyknics, which did not overlap on the Strömberg-Index of body build. Although no important relationship of this dichotomy to choice of colour was found, leptosomes structured considerably more than pyknics in the beginning.

Conrad (1954), being as critical about colour choice and abnormality as Brengelmann (1953a), proceeded to investigate differences in test attitude. His contention is that abnormals choose more at random and should therefore differentiate from normals regarding deviation from the stimulus colour norm (theoretical norm). This was criticized by Brengelmann (1956a), who obtained no significant differentiation with regard to deviations from the stimulus norm. Deviations from an independently established normal norm (empirical norm) were, however, significantly greater for neurotics, depressives and schizophrenics than for normals (Brengelmann, 1957c), indicating that abnormals follow test instructions in a more variable manner.

COLOUR-STAR TEST (FARBSTERNTTEST, SEYFRIED)

This test, designed by the Austrian psychologist Seyfried, is very similar to the Colour-Pyramid Test. Instead of a pyramid form, a star-shaped pattern is used. This pattern consists of twenty equally large equilateral triangles. Highly significant differences were found between one hundred normals and thirty-five acute schizophrenics for both "structure" (Chi-square of 26.439, 1 d.f.) and "orderliness" (Chi-square of 27.068, 1 d.f.). However, an unidentified number of these patients was receiving electro-shock treatment (Bullinger and Seyfried, 1954).

A group of fifty normal girls was compared with twenty each of sexually and generally maladjusted girls (Bullinger and Seyfried, 1955). No significant differences were found in pattern construction. In yet another study, thirty depressed patients, eighteen of whom were "endogenous" depressions, were compared with fifty normals, all female subjects (Seyfried, 1955). No significant differences were obtained between groups with regard to carpets, layers, and structures (Chi-square of 3.349, 2 d.f.). A simple behavioural tendency was observed, namely the difference between subjects who turn stimulus elements with their fingers before putting them down versus those who put them down unhesitatingly, which discriminated at the one per cent level (Chi-square of 8.495, 1 d.f.). Depressives turned the stimuli more often. (All these results were recomputed by the present author.)

BUNCH-OF-GRAPES TEST (TEST "DEL GRAPPOLO D'UVA," SANGUINETI AND SIGURTA, 1951)

This is a modification of Lamparter's (Kroh School, Germany) colour-form reaction test, applied to

abnormal psychology. It is similar to the two preceding tests; a number of circular shapes ("grapes"), varying in colour and size, and rectangular strips of paper ("branches") are offered to the subject to construct a bunch of grapes (Fig. 3.10). The number of shapes chosen and the space occupied by the subject to construct a pattern is not standardized.

EVALUATION

Differentiation between normals and abnormals, adjusted and maladjusted, or between clinical categories, has been partly significant, partly doubtful. The trends of means have been consistent. It may be said that these results have, though insufficient, been more encouraging than those reported in Sect. II. It

FIG. 3.10. RESPONSES TO THE BUNCH-OF-GRAPES TEST

Apart from colour choice, responses are mainly rated for symmetry, stereotypy, loss of form, circular shape, relief and size.

Considerable differences have been reported among neurotics, depressives, psychopaths, manics and various subgroups of schizophrenics by each of the following authors: Sanguineti and Sigurta (1951), Treves and Papo (1952), Lusso (1954), and Laricchia and Beretta (1954). The results were not assessed for significance, percentages only being given. These vary to a considerable degree between authors, but despite this, there has been no criticism of each other's work and the authors agree on the clinical usefulness of this test. As the scores depend on ratings whose reliability is unknown, no attempt was made by the present author to recompute the percentages given and assess them for significance.

4—(B.—E.8)

may be argued that the rather stricter experimental limitations improved, if anything, the significance of results. In nearly all cases, however, sampling has been insufficiently controlled and final judgement must be reserved.

More or less incidental findings such as larger scatter in conduct disturbance, compared with other neurotic symptoms (Mosaic Test); greater variability of abnormals in response to the Colour Pyramid Test; and greater hesitation, or indecision, of depressives compared with normals in the Colour-star Test, are of interest and should be followed up.

The advantages of the manipulative tests described appear to be twofold: these are standardization of procedure and the restriction of number of scores taken. Though both these advantages are basically welcome, all the tests quoted have this in common,

that no empirical development in construction has taken place. The tests were constructed rationally and have maintained their structure regardless of the results obtained. It appears unreasonable to expect a rationally conceived test to function at its optimum level. The same applies to the actual scores taken. Though few in number, no intercorrelations appear to have been computed.

It appears to be of distinct advantage that the application of the test can be repeated. This offers an opportunity of investigating response variability between sessions. Reliability itself has not been systematically assessed. Significant test-retest changes have, however, been reported for the Colour Pyramid Test (Conrad and Juncker, 1954). The psychological meaning of these is being investigated in the Heiss School using so-called "sequence analysis."

Handwriting

It is generally assumed by graphologists that form and style of handwriting are expressive of personality and that individual differences and changes vary with corresponding differences and changes in personality. If this is true, graphology should claim a unique position in diagnosing abnormality, as the change from normal to abnormal, and vice versa, could easily be studied from existing records.

The results of studies of handwriting have frequently been reviewed (Allport and Vernon, 1933; Lewinson and Zubin, 1942; Eysenck, 1945; Marum, 1945; Secord, 1949; Bell, 1951; Vernon, 1953). From the literature it appears that, on the European Continent, *a priori* theorizing (Pophal, 1949) and the non-statistical use of graphology (Heiss, 1950) still dominate the field. Methods adapted in Anglo-American countries have had little influence, as is shown by Klages' (1949a) 23rd edition of *Handschrift und Charakter*, which has hardly changed since 1916. In Anglo-American countries, the early enthusiasm of scientifically minded psychologists, which was aroused mainly through contact with displaced European graphologists, has been reduced to practically zero during the last decade. The *main results* to date, regardless of the methods used, are listed below.

By far the greatest number of studies has been completed in the field of *normal personality*, usually matching personality sketches, or case studies, with assessments from handwriting. Correlations between handwriting and personality questionnaires, or ratings, are of greater interest because these can be understood more easily in terms of dimensional measurement of personality. Slightly positive results were obtained in the assessment of personal values (Cantril, Rand and Allport, 1933); neuroticism and ascendance-submission (Harvey, 1934); neuroticism (Simon and Schönfeld, 1935; Eysenck, 1945) and emotionality-

introversion (Land, 1924). In the last experiment, small capital letters and extreme backhand and downhill writing were found to be significantly related to the trait quoted.

Middleton (1939, 1941) had untrained judges estimate dominance, neuroticism, self-confidence and sociability from handwriting. The results were largely negative. Pascal (1943b) obtained a number of significant correlations, which were not cross-validated, between handwriting and personality variables and these will be discussed below. The results of various other psychological tests have remained rather inconclusive (Enke, 1938; Schade, 1939; Super, 1941; Crider, 1941). Some significant correlations between handwriting and speech were obtained by Grünwald (1954), but again, these were not cross-validated.

In the field of *abnormality*, graphology has been applied to various psychiatric categories. Mayer-Benz (1929) achieved considerable agreement between the clinical diagnosis of psychopathy and handwriting analysis. In one study made by H. J. Eysenck (1945) a graphologist was able to match her analyses with personality diagnoses written by psychiatrists. In a later investigation by the same author, a different graphologist could not differentiate significantly between the handwriting of neurotics and normals. Lewinson predicted failure in college and maladjustment to a significant extent (Munroe, Lewinson and Waehner, 1944). Similar predictions of adjustment problems in students made by Wells (1946, 1949) were not very satisfactory.

Psychotic characteristics of handwriting were described by Lewinson (1940) as follows: (a) disturbed rhythm (irregularity or rigidity); (b) lack of balance between bond and release and (c) arrhythmic distribution (stereotype or beyond control). Further results suggestive of differences between psychotics and other groups are provided by Paskind and Brown (1940) and Mandowsky (1934). Schorsch (1939) believes that pre-psychotic writing differs from the corresponding writing of the same persons in the psychotic state. This was not confirmed by Legrün (1939).

The assessment of the *usefulness of handwriting analysis* is, for various reasons, an unrewarding task. If the opinion of eminent graphologists is followed, the claims are inconsistent and will lead us nowhere. If, in particular, Klages' (1949b) decision is taken seriously that psychological illness can "on principle not be detected from handwriting," most of the work quoted should not have been performed. If the actual results, regardless of the methods used, are taken as an indication little importance can be attached to graphology in the assessment of personality, or abnormality.

It has become a tradition with reviewers of handwriting to point to the difference between the *intuitive*, *subjective* or *holistic*, and the *analytic*, *objective* approach. An example of each of these two methods is given in Table III.5. It is noted that the intuitive approach makes use of a number of characteristics which are very difficult to measure directly, but may be of great importance.

In terms of results the holistic method has usually fared better. With the subjective method, the judge is presented with handwriting specimens and a set of character sketches, or other characteristics of personality, which are to be matched. With this technique even laymen can sometimes match slightly better than chance, and expert graphologists better still. This conclusion has been accepted for decades.

More significant, however, is the fact that *criticism of the matching technique*, on which the claims of intuitive graphology are almost entirely based, has increased. Apart from the meticulous precautions which must be taken to avoid the real danger of both artificial consistency and validity due to the effects of extraneous clues, the following are the main drawbacks of the matching technique. Success depends on the heterogeneity of subjects and tends to disappear with relatively homogeneous groups; not more than five or six subjects can be matched at a time; no continuous scores or reliable rankings can be obtained over larger groups; raters vary considerably in their use of cues and, finally, it is impossible to define which of the various traits of personality are assessed. Methodological criticism has thus increased out of proportion to the modest success claimed and has, for that reason, rendered the holistic-analytic controversy a pseudo-problem.

Any reviewer would feel more light-hearted about this statement if analytic handwriting analysis had shown greater promise. This is not the case. Lewinson and Zubin (1942) have elaborated a number of objectively scorable scales and certain combined ratio scores which are claimed to be more representative of the actual appearance of writing than simple analytical measures. This may be considered an important landmark. However, two experiments have been made since, using these or similar scoring procedures, with no demonstrable success.

Pascal (1943b) computed rank order correlations between twenty-two handwriting variables and each of thirty-six personality variables, derived from Murray's (1938) *Explorations in Personality*. Each of the twenty-two subjects had been investigated for thirty-six hours. Of the seven hundred and ninety-two intercorrelations, nine coefficients were significant at the one-per-cent level and thirty-two at the five-per-cent level. These results could easily have arisen by chance. Pascal then proceeded, helped by multiple

correlations, to obtain a number of significant relationships between handwriting and personality. However, by selecting the highest coefficients, without cross-validation, he made capital of chance error and his results cannot be accepted as conclusive.

In the second type of analytical experiment made by Secord (1949), handwriting samples of fifty students were matched in sets of five with T.A.T. stories by five judges. On average, somewhat less than two matchings in each set of five were correct. In addition, Lewinson's claim of specific relationships between twenty-two handwriting and personality variables was tested (*Handwriting Analysis*, Chap. IX). No correlation was found to be significant at the five-per-cent level ($N = 15$).

The analytic approach, as it stands today, cannot claim to have added any positive result to the analysis of handwriting. While, however, the possibilities of intuitive handwriting analysis appear exhausted, objective procedures have hardly been applied properly. Cross-validation of Pascal's study, for example, may reveal a reasonable amount of consistency in results and may provide valuable hints for the selection of handwriting and personality variables.

The study of relationships between objectively measured handwriting and other expressive movement variables, appears to be of much greater promise, provided the personality and/or abnormality correlates of the latter are—to some extent at least—known. This approach which, with the construction of the F.R.T. (Sect. IV), is now feasible would remove the deficiencies in matching and rating. Additionally, more recently developed personality questionnaires of improved validity with respect to both personality and expressive movement, may be expected to be helpful. It is now known, for example, that when neurotics or neuroticism questionnaires have been used as criteria, no success has been obtained in the objective measurement of expressive movement, but that both extraversion and rigidity questionnaires have proved to be useful (Sect. IV). These latter two criteria, however, have not, so far, been used in handwriting analysis.

Some main points concerning handwriting analysis may now be *summarized*. *Intuitive analysis* has shown that handwriting can be diagnostic of normal and abnormal psychology. This method, however, is charged with a number of restricting deficiencies, already pointed out. In addition, *skill in analysis* is well known to vary widely even between experts. In the opinion of Vernon (1953), the amateur is "unlikely to give diagnosis of any value at all. Many so-called professionals are also inept, and there is no ready means of distinguishing the bad from the good."

Objective analysis has so far yielded no established correlates of handwriting. This approach, however,

TABLE III.5
PERSONALITY CORRELATES OF HANDWRITING

Upper part = intuitively conceived characteristics of various clinical categories (Marum, 1945).

Lower part = correlations between measured items and personality ratings, significant at the 5 per cent level (Pascal, 1943b).

1. Depression	Failing or fluctuating lines; heavy pressure, or particularly thin, timid, and irregular pressure; slanting to left; signature placed toward middle or left of paper; small letters; diminished height of capital letters; corrections; slow writing. (At least two of these signs have been found in cases where depression is stated.)
2. Anxiety	Narrow distances between words; narrow distances between lines; words end abruptly; ellipses (in o, a, g, etc.) may be compressed by next letter; lines begin at extreme left without a margin; signatures may be on left half of paper; slant and flourishes may be to the left; pressure either heavy or there are irregular losses of pressure; writing small and slow with occasional abrupt loss of height.
3. Obsessional neurosis	Regularity and rigidity with some artificiality of style; narrowness; small letter formation; touched-up letters; perpendicular direction, or slant to left, or irregularity of slant; wide distances between words combined with narrow letters, or extremely small distances between words and lines.
4. Hysteria	Two types: (a) irregularity of height, width, and slant; fluctuation of lines; indistinct, mixed ligature; (b) grotesque slant to left; exaggerated flourishes; heavy pressure; covering strokes; irregular connectedness; lack of proportion in accentuation of some letters, particularly initials.
6. Schizophrenia	Rigid, unnatural writing; sloping to left; covering strokes in middle zone; some tendency to threadlike ligature; exaggerated loops in lower zone; discrepancy between text and signature; increased heights of letters in middle zone at ends of words; large distances and horizontal strokes between words.

Item	Personality correlate
4. Upper projection (b, h, k, l)	(-) anxiety, (+) affiliation, (-) projectivity, (-) understanding, (+) play, (-) radical sentiments, (-) narcissism
5. Lower projection (g, j, q, y, z)	(-) abasement, (-) succorance, (+) counteraction, (-) radical sentiments
6. Total vertical expanse	(-) projectivity, (+) play
8. Primary width (m, n, u)	(+) sentence
9. Primary width range (mid-zone range* divided by mean of 8)	(+) nurturance
10. Mid-zone size ratio (mean of 8 divided by the mean of mid-zone height)	(+) dominance, (+) rejective, (+) projectivity, (+) intensity
11. Distance between letters	(-) ego ideal
12. Distance between words	(-) understanding, (+) play
13. Mid-zone fullness (width of o)	(-) exocachexion
15. Lower zone fullness (lower loops of g, j, q, y)	(+) projectivity, (-) play
16. Width of pen-stroke	(+) infavoidance, (-) nurturance, (-) exocachexion, (+) harm avoidance
20. I dot distance (horizontal deviation from letter)	(-) infavoidance
28. Angular connexion of letters	(+) infavoidance
39. Balance of projection (5 minus 4)	(-) abasement, (+) defendance, (+) counteraction, (+) dominance, (-) radical sentiments, (+) super ego integration

* Mid-zone range = difference between highest and lowest measures of mid-zone.

is not considered to have been put to proper experimental test. The fact that there is no established set of signs, or any other communicable method of scoring, specific to any demonstrable personality aspect applies to both the subjective and the objective approach.

The advantages of handwriting, its frequent availability over long periods of an individual's lifetime and its relatively unintentional character, together with the suggestion that the objective analysis remains incomplete until more recently developed criteria are used, may guarantee continued interest in graphology for some time.

More systematic analysis of various conditions may contribute towards validation. The effect of "spontaneous" versus "copy" writing (Castelnuovo-Tedesco, 1948), the effect of writing under stress and distraction (Stracke, 1933; Pohl, 1936; Ostermeyer, 1937; Keyes and Laffal, 1953), the effect of drugs whose validity in connexion with other expressive movement measures are known (Rabin, 1953; Brengelmann, 1958*a*, 1958*b*, 1958*c*), microscopic measurement, relationship to muscle tension, and the assessment of response set, or attitude while writing are quoted as examples.

IV. OBJECTIVE TESTS

In this section, a number of heterogeneous motor tests are discussed which, at present, have this in common that, in the main, they are objectively scored. They are classified as writing pressure, prismatic tracing, kinaesthetic drawing and figure reconstruction. Their most important *aims* are, *first*, to demonstrate reliable correlates of expressive movement in both personality and abnormality and, *second*, to suggest definitions of the role which motor attitudes or styles play in the performance tasks from which they are derived.

Various types of expressive movement, essentially independent of performance abilities and related practice effects, are found in a number of motor tests of the reaction, co-ordination, agility, strength, steadiness, etc., type. In certain tests involuntary expressive features are more apparent than in others, as in track tracing and pursuit rotor performance of a sufficiently high level of difficulty, in the Luria-type of association-motor response and in the Porteus Maze Test (Q-score). It appears much too early to raise the question of the generality of such expressive functions, which implies that motor style is essentially constant for a particular individual over a number of tests. However, the definition of *some* personality correlates of style and of *some* conditions necessary for the manifestation of certain styles should at least

In addition to the difficulties already pointed out, it would be easy to criticize most previous experiments on the basis of poor experimental control, item analysis and choice of criteria. Much more serious, however, in view of future work, is the limitation, quoted from Vernon (1953), that "only about a quarter of the population are sufficiently fluent writers to have developed a mature, individual style." A further complication is the fact that many handwriting specimens are difficult to measure objectively, at least on a number of a comprehensive set of signs.

The prospects for graphology do not appear bright in the light of the well-known fact that comparatively simple objective measures of movement characteristics provide much more reliable and valid measures of personality. The practising charlatan will, however, continue to claim "good" results, as pointed out long ago by Krüger and Zietz (1933). These authors submitted the same character sketch to a number of subjects claiming the sketch to be an expert opinion of their character; all subjects were convinced that the sketch represented a description of their own character.

suggest a way out of the confused picture that characterizes expression research today.

Writing Pressure

For decades it has been a standard claim that "the hands . . . , being the most frequently used expressive mechanism of the individual, will afford the best indication of the general level of the individual's tension" (Johnson, 1928), that "it is a common experience that the individuality of people . . . can be distinguished through characteristic patterns of muscular activity" (Ruesch, Finesinger and Schwab, 1940), and that "it is common knowledge that the neuromuscular *tonus* of man is affected by, and in turn affects, his personality and behaviour patterns" (Goldzicher Roman, 1950).

With large individual differences specific to personality, what more could be asked for, particularly as considerable improvement in apparatus has taken place during the last thirty years? The results, however, have hardly come up to expectation.

Originally, variations in pressure were judged directly from handwriting of drawing characteristics, or from impressions left on the writing-pad. Anastasi and Foley (1941) reported that anxiety states, chronic schizophrenics, and advanced catatonics, drew faint lines, which were interpreted as little pressure. Heavy

pressure was used by psychopaths and subjects suffering from various types of organic diseases. Uniform levels of pressure were typical of catatonics and the feeble-minded, whereas pressure variability was most frequently found in flexible and adaptable individuals. In children's paintings, according to Alschuler and Hattwick (1947), heavy strokes were said to be typical of assertiveness and light strokes of either low energy level, restraint, repression, fanciful imagination, or generous attitudes. Wolff (1946) preferred interpretation of the expressive kind. To him, oversharpe lines revealed "definiteness," determined strokes "high security," high pressure "vitality" and low pressure "weakness."

Early attempts at the direct measurement of writing pressure included the *carbon copy method*. With this fairly reliable method, ten sheets of unglazed onion skin paper and ten sheets of light weight carbon paper are arranged alternately. Involuntary writing or drawing point pressure may then be scored as the number of sheets through which writing penetrates (Baxter, 1927). Using this method, some suggestive results were obtained by Clarke (1950) who investigated emotional instability in sixty-eight normals and one hundred and twenty-nine neurotics. Point-pressure penetration scores were derived from three rather heterogeneous tests: motor perseveration (SZ alternation), mirror drawing, and signature writing. There was an insignificant but consistent tendency for neurotics to press harder than normals. This difference was mainly due to the hysterics, pressure, on average, increasing in the order, anxiety states-normals-hysterics. This appears in keeping with the subjective observations already reported.

The introduction of *pneumatic recording* has led to a number of developments, which have been reviewed by Davis (1942) and Courts (1942). The most important technical development was the introduction of concurrent measurement of point- and grip-pressure. Relatively constant and considerable individual differences in pressure were found by Duffy (1932) who also obtained correlations of near 0.5 with ratings of children's excitability and emotionality. Later on, using twelve measures of pressure and four measures of fluctuation, reliable individual differences and a certain amount of generality of this type of muscle tension were found repeatedly by the same author (Duffy, 1936). Ruesch and Finesinger (1943) obtained results rather similar to those already reported. Grip- and point-pressure during continuous movement of handwriting were investigated using forty patients of various psychiatric and neurologic diagnoses and twelve controls. The patients' scores, both on grip-pressure and a questionnaire aimed at measuring feelings of tension, were significantly higher than those of the controls. Additionally, a significant positive

correlation was found in both the neurotic and psychotic patients between feelings of neuromuscular tension and point-pressure. No correlation was found between feelings of *general* tension and any of the pressure readings.

Pascal (1943a), among other scores, correlated pressure and pressure-range, obtained from twenty-one men, with five personality traits, as rated by seven psychologists. The following results were obtained which, it must be kept in mind, were not cross-validated.

Correlations	Energy	Expression	Impulsion	Dominance	Determination
Pressure Range	0.60	0.53	0.41	0.33	0.18
Average Pressure	0.54	0.54	0.39	0.20	0.01

$r = 0.55$ for 1 per cent., 0.43 for 5 per cent level of significance

A number of correlations were significant, and this is provocative enough to be followed up. An interesting difference between sexes, which had already been observed by previous authors, was confirmed by Pascal. Adding ten female subjects to his male group, he found that men scored significantly higher on both average pressure and pressure range. Related findings derived from a different type of test are discussed under the heading "Figure Reconstruction Test" in this section.

The most extensive use of writing pressure since Krapelin's *Schriifwaage* appears to have been made in Kretschmer's laboratory, judged from various summary reports (Steinwachs, 1950, 1952, 1953). Work was concentrated on constitutional and developmental problems. Only more recently does it appear that grip- and point-pressure have been related to neurotic disorders, as well as to brain damage and epilepsy (Steinwachs, 1955), but no actual results have been reported to date. It may be interesting to find out whether this departure from the usual somatic criteria results in new theoretical developments within Kretschmer's system. In Kretschmer's latest, 20th ed. of *Körperbau und Charakter* (1951) writing pressure is still treated in the same way as it was by Enke (1929) thirty years ago. After considerably improving the technique used by Steinwachs (1951), Kretschmer states: "Results are in principle comparable to those of Enke" (op. cit., p. 257). This implies greater pressure for leptosomes and athletics, against pyknics, and increase of pressure with writing time in the order leptosomes-pyknics-athletics, as seen in Fig. 3.11. Unfortunately, significance of differences was not assessed and no parameters other than means were supplied.

Pophal, a prominent research graphologist, who holds a chair in graphology at the University of Hamburg (Germany), may be expected to contribute to the field of personality. While he is, however, an outstanding theoretician of graphology, his experiments appear to be more generally of a psychological and physiological kind. His latest report was on methodological developments and the effect of excitant and depressant drugs, as well as glutamic acid, on writing speed and pressure (1956). Excitant drugs were stated to increase grip- and point-pressure.

In summary, it may be said that evidence has been quoted which shows: (a) that writing pressure is greater in abnormals than in normals; (b) that, in neurotics, writing pressure may be stronger in hysterics than in dysthymics; (c) that certain personality traits involving strongly expressive characteristics may correlate positively with writing pressure and (d) that

FIG. 3.11. WRITING PRESSURE AS RELATED TO CONSTITUTIONAL TYPES
(From Kretschmer, 1951)

writing pressure is lower in pyknics than in leptosomes and athletics. Surprisingly little is known about the writing pressure of psychotics despite the fact that motor disturbances are clinically much more characteristic of this category. Although there is a certain amount of evidence that pressure of the kind described is related to emotional tension, hardly any conclusion

can be drawn as to its relationship to the basic dimensions of personality.

If results appear modest, activity in *apparatus construction* has been much more lively. Of the various reviews the most recent one by Luthe (1953) is

FIG. 3.12. TWO SAMPLE RECORDS OBTAINED FROM THE ELECTROSCRIPTOGRAPH

A = written test word *momom*; B = point-pressure,
C = grip-pressure, D = pressure difference.

(From Luthe, 1953)

mentioned. Mechanical-pneumatic recording appears to have lost its attraction, and electronic equipment to have taken its place. The method presented by von Bracken, Pungs and Riedel 1949 and von Bracken, 1952, enables micro-motoric speed and phase changes of pressure as well as the usual pressure scores to be analysed. Luthe's apparatus measures point- and grip-pressure, and also records the difference between these two measurements and claims advantage through the provision of an extra large writing plate. Both types of apparatus are very similar, using condenser capacity changes as equivalents of pressure exerted on stylus and writing plate, and recording these variations oscillographically. Sample records obtained with Luthe's "electroscriptograph" are shown in Fig. 3.12. To what extent these recent developments in apparatus construction will be reflected in validation remains to be seen.

Although *speed of writing* has been investigated many times it requires considerably more detailed analysis. This appears possible with the newer type of apparatus. At this point, Katz's (1948) "scripto-chronograph," which permits a different type of temporal analysis of individual letters directly from the written record, should be mentioned. The effect of various conditions, quoted in Sect. III on graphology, variability in letter writing and the effect of content on writing could be investigated with this apparatus. Essentially, the apparatus consists of a steel rod for writing, connected to a direct current source, writing paper impregnated with a colourless solution of potassium thiocyanate and an aluminium sheet underneath. The rod and aluminium sheet complete a circuit which is interrupted at predetermined intervals. Writing then appears not as a continuous line but as a series of dots or short lines, from which time sequence may be analysed.

There are a number of technical difficulties about measurement of writing pressure, as Luthe and others have already pointed out. Apart from these, it may be necessary and difficult to assess the effect of attitude, or set, on "involuntary" movement. In addition, as Pascal (1943a) has shown, pressure scores vary considerably with instructions to write with varying degrees of pressure, thus demonstrating the ease with which the results may be faked. It is also known that pressure varies significantly with the size of writing, with the type of stylus used and, presumably, also with the size of writing plate.

Although it has been much less investigated, writing pressure, or the "third dimension" of graphology, appears to hold out more promise than the analysis of handwriting itself. This may be due to the fact that scoring is objective and that pressure is far more independent of teaching and other environmental influences than are handwriting characteristics. It may also be a more sensitive measure of changes towards abnormality in comparison with overlearned handwriting performed under direct perceptual control.

Care must be taken to differentiate between *voluntary strength* and *involuntary pressure*. The former is recorded with ergographs, dynamometers, and the like. Strength has not been a very successful criterion in the assessing of personality (Moore and Sturm, 1952). It is said to be highly specific to tasks (Takala, 1953), and criticism has been made regarding reliability (Fautrel, 1954). The measurement of involuntary movement, as in writing pressure and the Luria type of apparatus, appears much more promising.

Prismatic Tracing

Experimental work on extent, magnitude and variability of error in motor performance has remained

comparatively limited (Siddall, Holding and Draper, 1957), and corresponding personality correlates have hardly been established. It is the aim, in the present section, to point out expressive movement characteristics derived from, but essentially independent of, motor tracing, and to some of their meanings in terms of personality or abnormality.

Three points considered important will be made. *Firstly*, tests of the kind discussed, relying on performance *per se*, have not proved very successful in personality measurement. *Secondly*, expressive movement type of scores, derived from the same performance tests, can be shown to be powerful indicators of personality. *Thirdly*, the use of psychiatric criteria alone, as traditionally exercised, should be abandoned as a method unless personality criteria are used concurrently. These may, at present, be of the questionnaire type until standardized objective criteria, derived from apparatus tests, are available.

It has been known for a long time that motor *performance* scores represent relatively poor and inconsistent indicators of personality. Significant differences, if anything, were mainly obtained with schizophrenics under conditions where experimental controls were insufficiently applied. Huston and Shakow (1948), for example, showed that the inferior performance of schizophrenics was attributable to their poorer degree of co-operation rather than to schizophrenia *per se*. On the other hand, if we turn to the applications of motor performance it may be argued from the experiments of Davis (*see* Chapter 2) that expressive movement, or the style of motor attitude, is of importance. Motor behaviour of gross overaction versus inertia was found to be a most important source of pilot error in the cockpit. Similarly, Venables (1955), using a motor task involving the movement of a pointer in relation to stimulus lights, described performance which was seen to fall on a continuum of overactivity-inertia.

Lazarus, Deese and Osler (1952), in their review, described variability, stereotyped responses and changes in overt activity as effects which accompanied stressful motor performance. This suggests additional types of measurement of motor expression which are impressive enough to demand closer examination by the personality investigator. Furthermore, S. B. G. Eysenck (1955) points to the difference between motor disorganization and inadequacy of response in psychotics, and emotional irregularity in neurotics. The suggested division of inadequacy-irregularity may be considered an important pointer to an improvement of method, which might help to solve the present deadlock in measurement of association-motor response in abnormals.

These considerations are taken to suggest that scores dealing with overt bodily motor expression are

more specific to personality than are performance measures. Accordingly, an experiment of motor tracing which was designed to measure apparently similar expressive variables was performed and may support this claim (Bregelmann, 1957b). In order to

largely independent questionnaire measures of personality, viz., extraversion, neuroticism and rigidity.

From other experiments, reported by H. J. Eysenck (1956a) and Star (1957), it is known that pursuit rotor performance and rate of increase in performance did

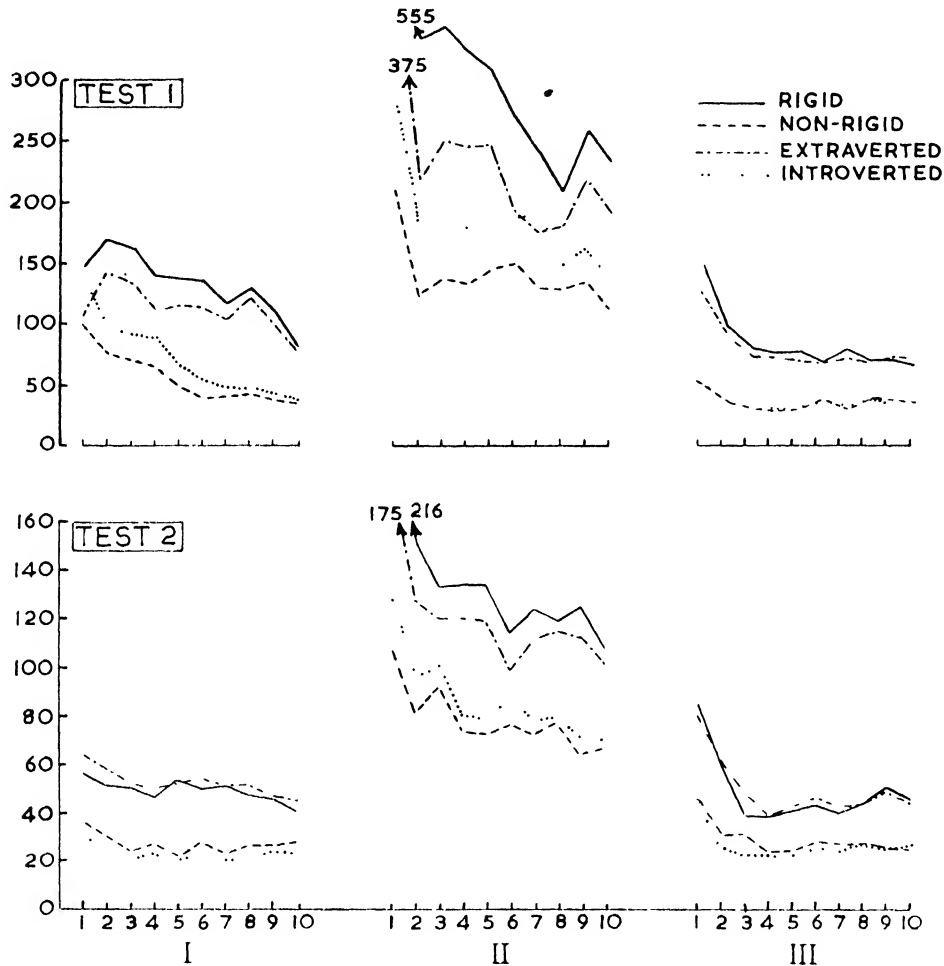

FIG. 3.13. RATIO ERROR-CORRECT TRACING WHILE WEARING PRISMATIC INVERSION LENSES

This is significantly related to extraversion and rigidity. I + III = left-right, II = upside-down inversion. Ten trials of sixty seconds per section.

(From Bregelmann, 1957b)

produce the desired phenomena, prismatic inversion lenses were used as means of stress. They were set to cause left-right and upside-down inversion of the visual field. Under these conditions, forty-nine normal subjects were asked to trace a curvy stimulus line with a pencil. Scores of correct performance, magnitude of error, variability, and a complex quality of movement form were derived and related to three

not provide important or lasting relationships to extraversion and neuroticism. It may be added that performance, or rate of increase in performance, was consistently slightly lower for extraverts than for introverts in the beginning. With prolonged practice, differences in means between these groups tended to decrease. It is important to state this, as the prismatic tracing results, presently described, were exactly of the

same nature as far as *correct* performance is concerned. (The pursuit rotor also provided a measure of correct performances.)

The important point is that, while correct performance on the prismatic tracing task yielded no significant correlations with any of the personality criteria used, all remaining measures were clearly significant

in a rather specific manner. They could, with certain reservations, be repeated on retest after two or three days. The *first result*, showing the *ratio of error over correct performance*, is presented in Fig. 3.13. Correct performance itself was not, but error performance was, significantly related to both extraversion and rigidity. The neuroticism factor is left out of consideration because of insignificant results throughout. Subgroups were created simply by dividing the entire sample of forty-nine subjects into two practically equal groups on the basis of the relevant questionnaire scores. Differences between subgroups, shown in the figure, were significant at the one-per-cent level for both extraversion and rigidity.

This figure shows, firstly, a similar relationship of both extraversion and rigidity to excess of error, as represented by the ratio score. Highly rigid and extraverted subjects scored higher. Secondly, within the left-right and upside-down inversion performances, relationships were initially higher for rigidity and decreased more rapidly with practice. It appears that over-reaction of this type is particularly specific to rigidity at the beginning of a difficult task and when a changeover to a different and more difficult condition takes place.

A *second result* is shown in Fig. 3.14. It concerns variability, defined as the mean deviation of individual trials from a section mean. (Sections I, II, III consisted of ten trials of sixty-seconds duration each.) Variability of correct performance did not differentiate significantly between any of the subgroups; for variability of error, *t*-ratios are shown in Table III.6.

From the point of view of measurement, the significant finding, again, was that the score derived from the traditional type of correct performance measure remained insignificant, whereas variability of error yielded results. It is also noted that variability decreased significantly with practice for rigidity only.

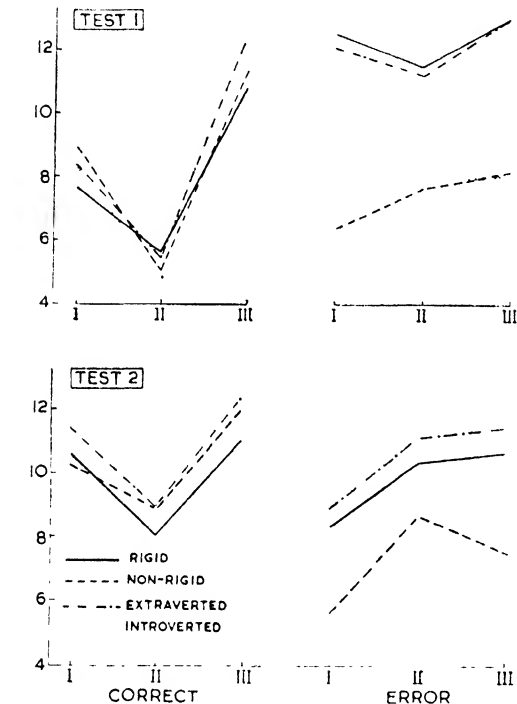

FIG. 3.14. VARIABILITY OF ERROR PERFORMANCE CORRELATES POSITIVELY WITH EXTRAVERSION AND RIGIDITY
Results for variability of correct performance are insignificant.
(From Brengelmann, 1957b)

TABLE III.6
VARIABILITY IN EXTENT OF ERROR DIFFERENTIATED SIGNIFICANTLY BETWEEN HIGH AND LOW RIGID, AS WELL AS BETWEEN EXTRAVERTED AND INTROVERTED SUBJECTS

(From Brengelmann, 1957b)

Variability of error	First test			Repeat test		
	I	II	III	I	II	III
24 High v. 25 low rigid	3.69 (0.1 per cent)	2.37 (5 per cent)	2.48 (2 per cent)	N.S. (10 per cent)	N.S.	N.S. (10 per cent)
24 Extraverted v. 25 introverted	3.08 (1 per cent)	2.09 (5 per cent)	2.53 (2 per cent)	2.75 (1 per cent)	N.S.	2.90 (1 per cent)

Significance levels in brackets.
I, II, III = sections of ten trials each of prismatic tracing

During the repeat test, significant differences were obtained exclusively between the extraverted and introverted subjects (Sects. I and III).

Error and variability of error may be essentially related measures, judged by the similarity of their results. However, it has been possible to derive a score of complex movement quality which was specific to rigidity and not to extraversion and neuroticism. Because of its complex character, this score had to be assessed. As was shown above, extraverted and highly rigid subjects were similar in the extent of error made when following the direction of the stimulus track. Additionally, subjects varied widely in sideward movements or, roughly speaking, in the extent of error made at right angles to the stimulus track. This error type was rated as "angular-excessive" against "smooth-restrained." Although many extraverted subjects made excessive errors, they were preponderantly of the "smooth" kind, whereas rigid subjects were characterized by "angular" movements. This rating significantly differentiated between three degrees of rigidity, as shown in Table III.7, not however between the subgroups formed on the basis of the extraversion and neuroticism scores. Two raters were asked to choose one third of all subjects for each of the extreme reactions, leaving the remaining subjects as a medium group. The ratings proved to be adequately reliable.

TABLE III.7

"ANGULAR-EXCESSIVE" MOVEMENT FORM DISCRIMINATED SIGNIFICANTLY BETWEEN SUBGROUPS OF RIGIDITY, NOT HOWEVER BETWEEN THOSE OF EXTRAVERSION AND NEUROTICISM

(From Brengelmann, 1957b)

Movement form (sideward error)	Smooth- restrained	Medium group	Angular- excessive	N
High rigid . . .	3	8	13	24
Low rigid . . .	14	8	3	25
N	17	16	16	49

$\chi^2 = 13.388$ (2 d.f.) Significant at 0.1 per cent level.

The results presented in this section may be summarized in the following statements. Scores of correct performance were not related significantly to three largely independent questionnaire criteria of extraversion, neuroticism and rigidity. Three scores derived from prismatic error tracing, error as such, variability of error and a rating of "smooth-restrained" versus "angular-excessive" movement form revealed differential relationships with both extraversion and rigidity.

These results are taken to throw new light on the widely used test of mirror tracing, which is described in Chapter 2 by Yates. The fact that mirror tracing has, for such a long time, not established any consistent results related to personality and abnormal criteria may have two explanations. Firstly, the type of mirror-tracing score traditionally used is unproductive. Scores of the kind described in the present section should be used instead. Secondly, the criteria of abnormality employed hitherto are insufficient. Because there was a lack of significant correlations between prismatic tracing and neuroticism, and because of the wrong choice of criterion groups, the frequently attempted differentiation between neurotics and normals may have failed. If abnormal groups are tested, personality questionnaires of the kind described in the present section should be employed.

In addition, the present results may be of use to investigators who study motor performance as a whole from a point of view excluding personality. This, in particular, may be true for research where complex motor functions are investigated by practice stages, as by Fleishman and Hempel (1954, 1955), because of an indication of specific time relationships between heterogeneous criteria of personality and certain aspects of behaviour in performance.

"Kinaesthetic" Drawing

Complex drawing techniques may have proved failures in the assessment of abnormality largely for the following three reasons: subjectivity of assessment, heterogeneity between the numerous items and dependence on artistic excellence in performance. If these sources of error are eliminated, considerable improvement may result and satisfy the usually agreed feeling of investigators that "there is something to expressive movement which is difficult to extract."

THE MIRA "MYOKINETIC" TEST (P.M.K.)

The demands of error control described above are, to a large extent though not entirely, met by the "myokinetic" type of test, or P.M.K., as constructed by Mira (1940).

Tests of this kind require the subject to start simple movement forms printed on the response paper, using full visual controls. After this, vision is blocked and the subject is required to continue the initiated movement which is now kinaesthetically guided.

Although the P.M.K. is, to a great extent, objectively scored, a substantial drawback is attached to it on account of the great number of subscores. This test requires the completion of the following types of drawings: lineograms, zig-zags, staircase-like forms, circles, chains of rings, parallels towards and away from the subject, and U-shaped figures. Each of these

categories is drawn with both the right and the left hand. Records are then scored for "primary" and "secondary" deviations, and each of these records is again scored for vertical, sagittal and horizontal

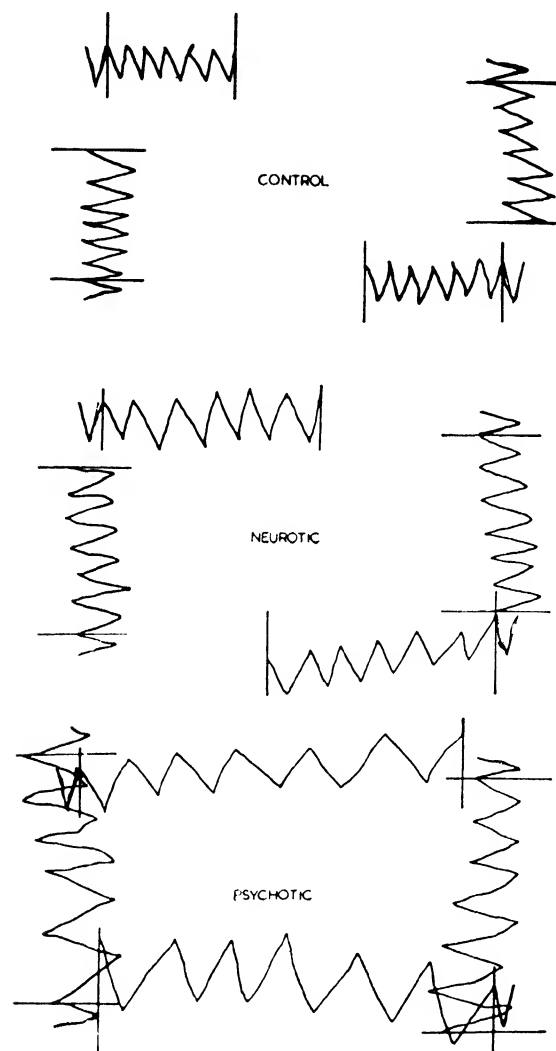

FIG. 3.15. SIMPLE BLINDFOLDED ("KINAESTHETIC") MOVEMENTS ARE LARGER FOR PSYCHOTICS THAN FOR NEUROTICS AND NORMALS

(S. B. G. Eysenck, unpublished)

deviations. Certain scores of size, density and axial deviation are added.

Takala (1953) has taken considerable pains to investigate the reliability and interrelations of test scores. As might be expected, a large number of reliabilities was doubtful. For sixty-eight categories

coefficients varied between 0.07 and 0.69. More than fifty were lower than 0.5 and only two higher than 0.6. Intercorrelations were, with few exceptions, positive and frequently significant. Factor analysis suggested that the numerous test scores might be profitably reduced to three factors. In practical application, this is far too complicated a task to be considered seriously. However, valuable hints for test reconstruction may be received from this study.

Takala also correlated P.M.K. scores with questionnaires, ratings and other personality assessments. The results were rather meagre and not cross-validated. As most of the original papers appeared in South American journals not accessible to the present author, the reader is referred to the reviews prepared by Takala (1953) and Stern (1954). In his most recently published test manual, Mira (1957) quotes about a hundred and thirty references. The investigations were mainly of the clinical, interpretative type. The relationships of scores to projective test results, occupational, intellectual and racial criteria are frequently discussed. Little emphasis has been placed on investigating experimentally the effects of clinical categories or objective personality criteria.

Mira claims, however, that his test measures the following characteristics: constitutional, genotypic reaction; transient, phenotypic reaction; intrapsychic coherence; aggression; depression-elation; extra-tension-intotension; constitutional emotivity; anxious impatience and constriction; excitation, inhibition and instability; constancy, or reaction rigidity; intellectual development; situational conflict and pathological alterations. As, with the exception of intelligence, no objective definition of the various personality characteristics mentioned has been given, the correctness of these claims cannot easily be assessed.

There are some points which require attention before more rigorously controlled research can be performed. As in Takala's work, reliability of test items varied extensively and was, on average, unacceptably low (0.5). Consequently, there is a considerable instability of norms between normal samples and the pattern of item intercorrelation appears to depart significantly from that found by Takala. No means and variances were provided for personality or abnormal functional criteria. The relationship to intelligence which, on a number of items is claimed to be high, requires a more objective and systematic treatment.

Like nearly all other tests described, the P.M.K. has not undergone any essential change since its initial conception. The technique requires, however, considerable revision by determining basic scores of high reliability which, in all likelihood, will be few in number.

SIMPLE BLINDFOLDED DRAWING

Simple drawing tests, depending on kinaesthetic guidance, were employed long before Mira constructed his P.M.K. (Allport and Vernon, 1933). In such tests, subjects were asked to draw three circles, waves, squares, etc., blindfolded. Reproductions were scored simply for size, amplitude, wave length, etc. The repeat reliability of this task was estimated to be 0.76 (Eisenberg, 1937). This is considerably higher than for Mira's P.M.K. Although it may be argued that this test is far too simple to be of great use in the face of the great complexity of expressive movement, it has stood its ground for what it measures extremely well. H. J. Eysenck (1952*a*, 1952*b*) and S. B. G. Eysenck (1956) consistently obtained highly significant differences between normals, neurotics and psychotics, as may be seen from Table III.8. Examples of test responses are given in Fig. 3.15. Further advantages are that this test is practically independent of intelligence and also very slightly related to age.

borated in various ways by the present author. Drawings of a square shape (1957*a*) and of a vase pattern (1955*a*), as used in a learning experiment, increased in size in the order normals-neurotics-psychotics. The same applied to a blindfolded test of tactual distance judgement of the Kundt type (1957*a*). Subjects were requested first to move slowly with their fingers over the "filled," or inspection, part of the stimulus and then to continue slowly on the "empty," or comparison, part until the size of the inspection part was subjectively equalled. Again, despite the fact that judgement was involved, scores increased significantly in the order normals-neurotics-psychotics. On two occasions, however, involving different types of tests, extent of movement increased in the order normals-psychotics-neurotics (Bregelmann, 1955*a*, Fig. 1; Bregelmann, 1957*a*, Table III.2). This time, no slow movement instruction was given. These results are simply shown to suggest that either type or test or instruction may affect movement responses.

TABLE III.8

SIMPLE EXPRESSIVE MOVEMENT TEST SERVING AS A RELIABLE MEASURE OF "PSYCHOTICISM"

(From S. B. G. Eysenck, 1956)

Average wave amplitude	Controls		Neurotics		Psychotics		F-ratio significance
	\bar{x}	s ²	\bar{x}	s ²	\bar{x}	s ²	
1	21.8	12.6	23.7	20.2	26.6	35.2	0.1 per cent
2	22.4	14.6	—	—	26.7	30.8	0.1 per cent
3	25.1	26.0	25.2	32.2	—	—	N.S.
Average wave length							
1	88.7	465.5	100.5	570.5	110.2	823.7	0.1 per cent
2	89.3	440.9	—	—	108.9	963.2	0.1 per cent
3	100.2	509.3	95.9	640.8	—	—	N.S.

1. = S. B. G. Eysenck, (1956); 2. = H. J. Eysenck, (1952*a*); 3. = H. J. Eysenck, (1952*b*).

The conclusion from this table would be that differences between groups were mainly due to the psychotics, as no consistent differences were obtained between normals and neurotics. Similarly, Crown (1953) failed to differentiate significantly between normals and tiqueurs. Within neurotics, anxiety states and hysterics were not found to be significantly different (Eysenck, 1952*b*).

OTHER MOVEMENT TESTS

An assortment of various types of tests is referred to because of a certain similarity of results. Firstly, findings reported in the previous section were corro-

The *significance of results*, presented in this section, is *assessed* in the following statements. *Firstly*, as shown by the Mira Myokinetic Test, it is not sufficient to construct an objectively scorable expressive movement test. Simplicity and reliability should be considered before everything else. *Secondly*, as regards simple, objectively scorable kinaesthetic drawing, it has been shown convincingly that this type of test measures "psychoticism" in a reliable manner. No significant differences were obtained between normals and neurotics, nor between neurotic categories. The reader should not overlook the fact that a test of greatest simplicity and short duration has

achieved much better results than any of the complex drawing techniques discussed in Sects. II and III.

Figure Reconstruction Test (F.R.T.)

A number of considerations have led the present author to construct a test, called the Figure Reconstruction Test (F.R.T.), which largely meets the

FRT IMMEDIATE RECALL
SET OF 10 PATTERNS

FIG. 3.16. Top: F.R.T. SET OF TEN PATTERNS OF MODERATE LEVEL OF DIFFICULTY

Bottom: REPRODUCED PATTERN WITH STATEMENTS OF POSITIVE OR NEGATIVE CONFIDENCE IN CORRECTNESS OF PERFORMANCE

Two error scores: 1 = rotation, or axial displacement; 2 = distance, or radial error. Two expressive movement scores: 3 = size; 4 = distance of shapes from the centre.

(Bregelmann, 1958e, 1959a)

criticism levelled against other drawing techniques as follows. (a) The test items to be drawn are of the simplest kind, to exclude the effect of drawing skill. (b) Scoring is entirely objective. (c) The test is constructed so as to be repeatable and yield high degrees of reliability. (d) The test is disguised as a learning or recall test to divert attention from movement. (e) The test restricts the number of drawing scores to a minimum, yet permits comprehensive analysis of common score categories, including intra-individual measures of variability. This avoids that abundance of intercorrelated items which are difficult to combine directly (Mira, P.M.K., B.G.T.) as well as a too great simplicity with limited scope for analysis (e.g. draw a circle, square, etc.). (f) The test permits the scoring of expressive movement characteristics to be independent of accompanying error. (g) Portions of the test may be analysed separately to assess the effects of feelings of certainty, or confidence, connected with the performance aspect of the F.R.T., on movement characteristics.

The F.R.T. which measures learning, recall and recognition (Bregelmann, 1956b, 1958e, 1958f, 1959a), as well as expressive movement, requires reproductions of exposed patterns of simple geometric shapes (circle, triangle, square, etc.) to be drawn from memory. Shapes are reproduced around a central reference point provided on the response sheets, as shown in Fig. 3.16. This figure shows a recall version of moderate level of difficulty. One such test set consists of ten patterns of five shapes each, distributed evenly over the stimulus surface (upper portion of the figure). At the bottom, an example of a drawn reproduction is shown including a description of some basic scores, as well as one of four degrees of certainty (+2, +1, -1, or -2) added to each of the reproduced shapes. These marks indicate how certain subject felt about the correct placing from memory of the individual items.

There are two basic measures derived from such drawings, the actual *size* of the individual shapes and their *distance* from the central reference point; both measures are taken in millimetres. In addition, the *spread* of shapes between distances and the *variability* of size and distance between trials form important scores among a few others.

Some of the more important results, all cross-validated, are now described. *Firstly*, in the initial two experiments (Bregelmann and Marconi, 1958d), *size* was consistently larger in psychotics than in controls (Fig. 3.17). When the neurotics were divided into hysterics and dysthymics, hysterics drew consistently larger, but not significantly so. Both results are in agreement with Eysenck's findings from using a simple kinaesthetic test (Sect. IV). It will be noticed, however, that score norms varied considerably

between these experiments; this occurred also in later tests. This difficulty was removed to a considerable extent by scoring *between trials variability* (Fig. 3.17), which provides essentially the same results at a much higher level of significance. Finally, by using the *ratio size variability/size* means were sufficiently identical between experiments for each of the four subgroups used, and significance of differences was retained

error) and *distance variability* (radial error). There is no reason to assume that axial error is differentially affected by individual differences in movement variability, as test items are equally spread over the stimulus surface and errors due to movements of this kind will cancel out. Systematic individual differences in radial expansion and variability, as determined by distance measures of the *non-error* type, have however

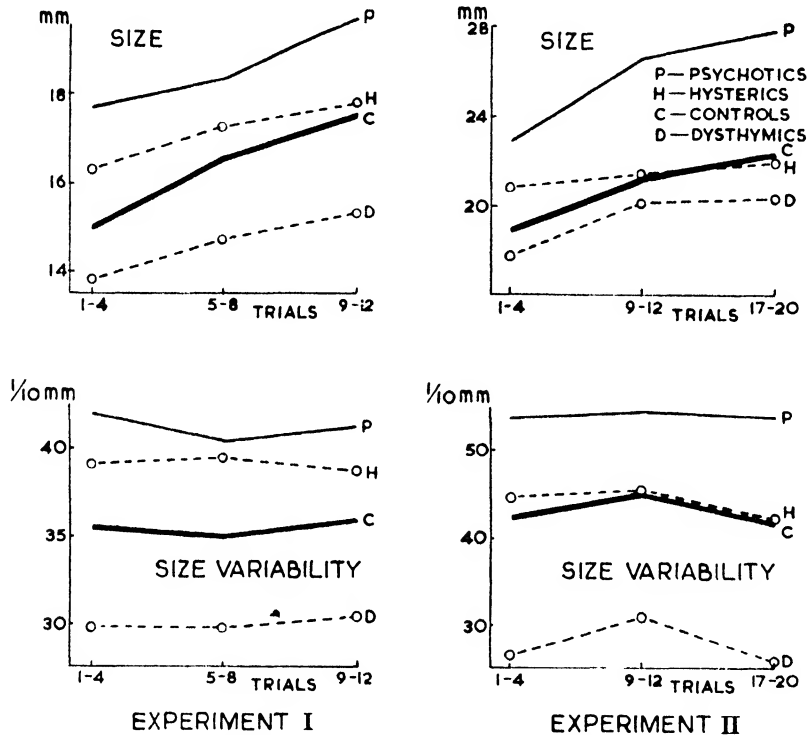

FIG. 3.17 THE SIZE OF REPRODUCED F.R.T. SHAPES IS DISTINCTLY LARGER FOR PSYCHOTICS THAN FOR NORMALS

Some relationship to hysteria/dysthymia is found.

(From Brengelmann and Marconi, 1958d)

between hysterics and dysthymics, as well as between psychotics and dysthymics.

In general, the result was that size and measures derived from size were primarily indicative of "psychoticism" and, in the second instance, of hysteria/dysthymia. Similarly measures of distance were rather more related to hysteria/dysthymia than to psychoticism.

A second problem thought to be of fundamental importance is the *interaction between error and expressive movement* (Brengelmann, 1959b). This is demonstrated by comparing the two types of error variabilities (between trials variability), which may be derived from the F.R.T., *rotation variability* (axial

been found, the relevant scores being highest for hysterics and psychotics. Radial movement variability may correspondingly interfere with radial error. This is, in fact, shown in Fig. 3.18 and Table III.9.

The results show similar types of learning curves for both rotation and distance variability. However, considerable differences in subgroups are found between the two error scores. As to rotation variability, no significant differences between hysterics and dysthymics are found at any stage of practice. With distance variability, however, differences between hysterics and dysthymics are not only significant but, contrary to general expectation from the learning point of view, predominantly so in the early practice

stages. This effect is, as predicted, also present in schizophrenics (compare trials 1-4 in Fig. 3.18) though not to a significant degree.

This result shows that, in drawing tasks, expressive movement may interfere significantly with correctness

FIG. 3.18. SIGNIFICANT DIFFERENCES IN DRAWING VARIABILITY (ERROR MEASURE) BETWEEN HYSTHERICS AND DYSTHYMICS, AS A FUNCTION OF ABSENCE (ROTATION) OR PRESENCE (DISTANCE) OF INTERFERENCE BY EXPRESSIVE MOVEMENT
(Bregelmann, unpublished)

of performance. With the F.R.T. such effects can be assessed. Error scores can be constructed which are either essentially free of such distortions or have been corrected for them. The criticism made of the Bender Gestalt Test that error and movement scores cannot be separated can now be better understood.

A third and a fourth point of further steps in validation are discussed jointly with Fig. 3.19. Careful inspection of results achieved with criteria hitherto used made a further reduction of the large variance, still unaccounted for, desirable. Two further criteria

TABLE III.9
SELECTIVE EFFECT OF EXPRESSIVE MOVEMENT
ON DISTANCE VARIABILITY

	Trials 1-4	Trials 17-20	Trials 1-4	Trials 17-20
Hysterics <i>v.</i> dysthymics (28 d.f.)	N.S.	N.S.	2.620 (2 per cent)	1.909 (10 per cent)
Schizophrenics <i>v.</i> normals (35 d.f.)	N.S.	3.884 (1 per cent)	N.S.	3.329 (1 per cent)

2 — trials tests.

were introduced, the first one being "rigidity," as measured by a combination of scores of the Nigniewitzky (1955) (Bregelmann, 1959a) Scale and the Soueiff (1958) extreme response set score. By this means rigidity was found to be statistically independent of extraversion. The second new criterion was "confidence" (Bregelmann, 1959a) as described above (compare Fig. 3.16). Results are now shown in Fig. 3.19.

It may be seen *firstly* that, in neurotics, both distance and standard deviation of distance decreased with rigidity (upper left portion). *Secondly*, examining the effects of "negative" and "positive confidence," distance was not consistently related to the dichotomy of negative/positive confidence. However, it was generally found, regardless of personality type, that nearly all subjects spread shapes bearing marks of negative confidence to a lesser degree than those with positive confidence (upper right portion of Fig. 3.19). There are, however, significant individual differences to this effect, which are specific to personality (lower half of Fig. 3.19).

The lower left portion shows that, with one exception, *means of distance* increase with extraversion. There are no great differences between negative and positive confidence, but score norms differ widely between sexes. The relationship between SD-distance for *negative confidence* and extraversion is exactly contrary between the sexes. However, a consistent and significant relationship with perfect subgroup placings is found for *positive confidence*. It appears from this that the introduction of the criterion "confidence" considerably improved measurement and stabilized test norms.

The last few points are of sufficient importance to be described anew in terms of *correlations between personality criteria and distance scores*, which are presented in Table III.10.

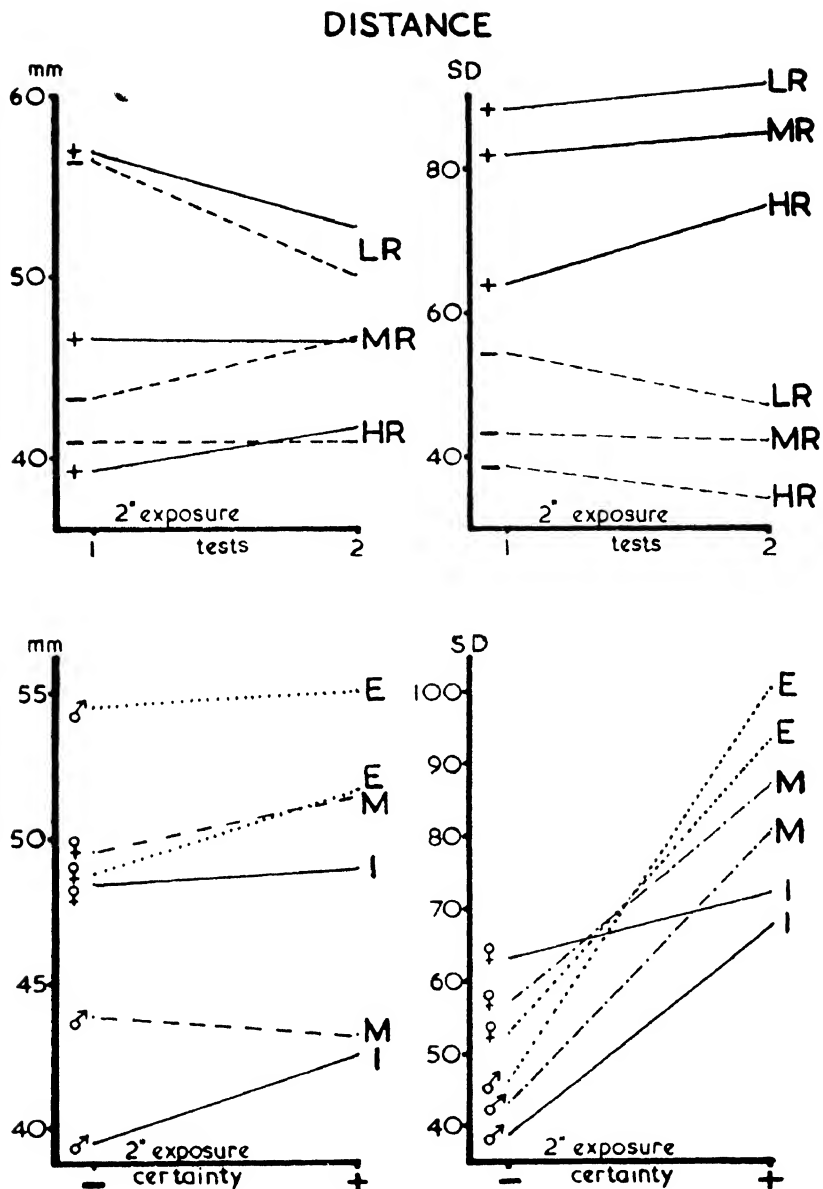

FIG. 3.19. *Top left:* DISTANCE DECREASES WITH DEGREE OF RIGIDITY ("CONSTRICION"). *Top right:* STANDARD DEVIATION OF DISTANCE DECREASES WITH DEGREE OF BOTH RIGIDITY AND NEGATIVE CONFIDENCE. *Bottom left:* DISTANCE INCREASES WITH EXTRAVERSION, WITH MEANS VARYING TO A CONSIDERABLE DEGREE. *Bottom right:* BETWEEN THE SEXES, ONLY SD-DISTANCE OF POSITIVE CERTAINTY IS CONSISTENTLY RELATED TO EXTRAVERSION

(N = 8 per subgroup)

LR = low rigidity	+ = positive	E = extraverted
MR = medium rigidity	- = negative certainty in	M = medium group
HR = high rigidity	memory performance	I = introverted

(Bregelmann, unpublished)

TABLE III.10
CORRELATIONS BETWEEN PERSONALITY CRITERIA AND DISTANCE SCORES
(SPREAD, OR EXPANSION)

	Distance	SD-distance	SD-distance separate for confidence		
			negative	positive	diff. between neg. and pos.
Extraversion	0.398†	0.364*	- 0.083	0.480†	0.542†
Rigidity (Nigniewitzky)	- 0.424†	- 0.506†	- 0.471†	- 0.352*	- 0.059
Extreme response set (+ 2 only, Soueiff)	- 0.347*	- 0.338*	- 0.191	- 0.275	- 0.158
Neuroticism	- 0.122	- 0.168	- 0.021	- 0.148	- 0.137
Negative confidence in reproduction	0.177	0.074	0.533†	- 0.267	- 0.611†

N = 48 neurotics (24 male, 24 female)

Significance: † = 1 per cent. * = 5 per cent level.

The following conclusions appear justified. (a) *Extraversion* correlates positively with distance and SD-distance. High spread of shapes, or SD-distance, appears to be largely an effect of positive confidence. The difference score between negative and positive confidence correlates highly with extraversion considering the fact that questionnaire and apparatus test scores are related. (b) *Rigidity* correlates negatively with distance and SD-distance. No differential effect for confidence is observed as in extraversion. Rigid subjects contract both the distance for negative as for positive confidence. *Extreme response set* functions similarly to rigidity, though somewhat less effectively. (c) There are no significant correlations for neuroticism. This is consistent with the fact that neurotics as a clinical group have not shown any expressive movement correlates as assessed by any of the drawing techniques discussed.

(d) The more *negative* confidence is in performance, the *greater* is spread for *negative* items and smaller for positive ones. This is the most significant and the most unusual result obtained in that it differs from both extraversion and rigidity without offering any immediate suggestion of the reason. Its large degree

of independence is demonstrated by a correlation of - 0.298 with extraversion and - 0.183 with rigidity. Clinically speaking, neurotics are considerably more *negative* in confidence than schizophrenics. Within the neurotic group, dysthymics are more negative than the hysterics.

It must be added that confidence is greatly, though strictly systematically, affected by exposure conditions. There is, however, no time to deal with this here. It may be added that a number of results are systematically dependent on other conditions, such as size of paper, practice effects, sex, etc. Anyone using the F.R.T. should be fully informed about these.

Briefly *summarizing* the evidence obtained with the F.R.T., it may be said with a reasonable degree of confidence that at least five more or less heterogeneous factors interfere with expressive movement of the type discussed. They are extraversion, rigidity, hysteria-dysthymia, schizophrenia and verbally expressed confidence in performance. For reasons stated, both the test and the criteria employed, in their effectiveness and scope, go beyond the majority of findings established in the field of drawing techniques.

GENERAL SUMMARY AND EVALUATION

Section I

The areas of expressive movement research originally most heavily favoured have yielded relatively little worth reporting. This can hardly be explained as due to difficulties in measurement, as many aspects of voice, speech, and gross bodily movements are amenable to objective investigation. It may be argued that the emphasis on judgement of "expressive" qualities of movement has distracted attention from the actual measurement of movement. Although judgement of movement has opened up extremely

fruitful avenues of research, emphasis on movement *per se* should be revived.

Abnormal or personality correlates of *gait*, *posture* and *facial movement* are practically unknown. *Gestures* are said to be expressive of "feeling" and "emotion." Particular types of gestures, nervous movements, are shown to be more frequent in neurotics than in normals. Nothing is known about *voice*, except for the suggestion that loudness and melism vary with body build, and intensity under stress with certain self-ratings of sensitivity. Various

speech characteristics are also said to be indicative of emotional states. Statements using such vague non-operational terms as "emotionality" indicate how little advance has been made over mere clinical observation. However, a certain amount of analysis of relevant conditions has been performed which should aid validation considerably.

Judgement of expression, on the contrary, has produced rather suggestive results. This method, originally intended to serve as a rating substitute for objective measurement, has been shown to reveal quite specific individual differences in *self-evaluation*, as well as in evaluating others. Schizophrenics rate their own expression (voice, face, writing, drawing) more favourably than do normals, provided they do not recognize them as their own. Nothing is known about neurotics. However, in the use of language, neurotics, possibly more than schizophrenics, make more *self-references* (personal pronouns) than normals. They also score high on the verb-adjective quotient, which may be indicative of internal states of tension. These facts suggest that self-esteem plays an important role, possibly of a causative kind. It may be surmised that certain hitherto unconnected areas like unconscious self-evaluation, extreme response set, confidence in performance, level of aspiration, use of pronouns, etc., are closely related. In addition to such rationally and easily recognizable relations, movement itself (e.g. size) may be conjectured in order to give clues to the inner attitude toward dimension or to "ego evaluation" (Liss, 1938). In one case an expressive movement score (standard deviation of distance, F.R.T., Sect. IV) has already shown significance and, as regards personality, specific relationships existing between self-evaluation and movement.

Attention has been focused on neurotics. Psychotics, however, have sometimes been shown to vary similarly to neurotics. In the case of "*vocabulary inflexibility*" they may be expected to score relatively highly. Differential behaviour between abnormals has not been investigated extensively. Within the neurotic field it has, on occasion, been shown that the hysterics behave rather differently from the anxiety and obsessive-compulsive states.

Section II

On account of their complex and impressionistic nature *products of art and free drawing techniques* are difficult to evaluate. The application of controls in the assessment of personality by means of free drawing and drawing completion tests have revealed numerous previous claims of validity to be unfounded. As regards personality and abnormality, none of these techniques can claim to have established useful validity. It has been suggested that objectification, as for example, by using the multiple-choice technique,

might remove some major sources of error in the assessment.

Section III

The copying version of the Bender-Gestalt Test has not been shown to measure personality, nor to differentiate between abnormal categories. Results in assessing abnormality have remained inconsistent, and the dependence on rating with all its serious drawbacks, the difficulty of constructing parallel test forms and, perhaps most important, the heterogeneous nature of the assessed scores, discourage future use of this test.

Manipulative tasks, as the Mosaic Test, the Colour Pyramid Test, the Colour-star Test and the Bunch-of-grapes Test, have revealed some suggestive results in differentiating between various groups of abnormals, and between normals and abnormals. The results require cross-validation throughout. Tests of this kind could, in the writer's opinion, be fairly easily adapted to yield objective measures of style of movement, which could justify their further use.

Handwriting analysis has so far not provided any communicable method of measuring personality or abnormality to a reasonable degree. The suggestion has been made that this is partly due to the choice of inefficient criteria. The permanence of handwriting records appears to be one good reason to continue in search for validation.

Section IV

Although less frequently used, objective tests of expressive movement have provided more consistent results. On *writing pressure*, neurotics scored higher than normals. This may be considered to agree with their known higher degree of muscle tension. Additionally, hysterics, pyknics and energetic-expressive-impulsive types of personality press harder than their opponents. An investigation of what these groups have in common in this respect might be rewarding.

Error and variability in tracing while wearing *prismatic lenses* were significantly related to both extraversion and rigidity. A rated score called "angular-excessive" versus "smooth-restrained" movement discriminated between extraverted and rigid subjects.

Simple blindfolded "*kinaesthetic*" drawing differentiates significantly and consistently between psychotics on the one hand, and neurotics and normals on the other. Because of its simplicity, this technique is restricted in its application.

The *Figure Reconstruction Test*, objectively scored and disguised as a memory test, is known to be related to at least five criteria of both personality and abnormality, to wit, extraversion, rigidity, hysteria/dysthymia, schizophrenia and a measure of certainty.

It may be noted that neuroticism, as measured by clinical groups of neurotics or by means of a questionnaire, is not of great importance.

Choice of Criteria

A comparison between earlier sections and Sect. IV reveals that there has been considerable improvement in validation as criteria have been changed, but that this has varied between criteria. Extraversion, rigidity and certainty, as used in some of these studies, have not, in fact, been applied to expressive movement before. The repeated finding that neuroticism played no significant role seems to support the argument that poor results have, at least in part, been due to the choice of too complex, or inadequate, criteria such as "emotionality," "adjustment," "instability," etc., which are generally considered to be associated with neuroticism.

With the F.R.T., certain reliable differences have however been found using clinical categories of neurosis and psychosis as criteria, but there was a large overlap between groups.

It would seem, from these considerations, that the exclusive use of clinical criteria of any kind should be abandoned. There is, however, evidence strong enough to suggest that personality criteria of the kind employed are at least as important as clinical diagnosis and should be used in addition to the latter.

Empirical Test Construction

The inflation in test production has been justly criticized by many workers. Personality tests, however, with the exception of questionnaires, are as a rule constructed on "rational" grounds, i.e. without proper *empirical* development. This appears incongruous with scientific procedure in general and has been shown to be unsuitable in the field of expressive movement. Tables III.7 and III.10, for example, demonstrate the empirical derivation of fundamentally important variables which could hardly have been predicted on theoretical grounds. Evidence on two types of error variabilities, as presented in Fig. 3.18, shows the empirically derived distinction between expressive movement-free and movement-influenced error scores to be of great importance. If, for example, this distinction had been considered in the construction of widely applied tests like the Bender-Gestalt Test, the confusion resulting from relative emphasis on theorizing might have been avoided.

Functional Analysis

Greater flexibility in choice of criteria and emphasis on empirical test construction are important, though not sufficient. Alone they do not offer adequate control of variables. Suggestions have been made that change in conditions may change the validity of voice

intensity (Sect. I), or of handwriting (Sect. III), or that exposure time may affect the effectiveness of movement scores (Brengelmann, 1958a). Striking examples of the modifying influence of task conditions have been discussed in connexion with unconscious evaluation of one's own expression (Epstein, Fig. 3.1) and with certainty, which is known to be intimately related to expressive movement (Table III.10; Brengelmann, unpublished results). Furthermore, movement variability could be shown to be both positively (Sect. IV) and negatively (Sect. IV) related to rigidity, a relation which may be a function of stressfulness of tasks. At the same time, correlations with extraversion were significantly positive throughout. From this evidence it is suggested that functional analysis, a method widely used in other biological sciences, should be introduced systematically to ascertain the conditions necessary to produce the phenomena studied.

General Recommendations

The last three points discussed, choice of inefficient criteria, use of heterogeneous test scores and disregard for conditional effects may explain why results have been so poor in a field rich in promise for personality work. Before other considerations, a higher regard for experimental procedures of the kind discussed appears necessary if basic functions of expressive movement and their personality or disease correlates are to be discovered.

The effect of such recommendations may be felt in fields where expressive movement is secondarily involved. Eysenck (1956a), Star (1957) and Brengelmann (1957b) found, for instance, that rate of improvement in tracking and tracing was, consistently, slightly negatively related to extraversion. This was taken to support Eysenck's learning theory involving certain assumptions concerning the cortical balance of excitation-inhibition (compare Eysenck, Casey and Trouton, 1957).

The tests used in the above studies involve, however, "expressive" movements of a kind likely to interfere with the actual motor performance, for which the theory was constructed. Both variability and extent of movement were demonstrated to be consistently and, as a rule, significantly related to extraversion. From this, it appears quite reasonable to assume that motor performance of extraverts tends to be less efficient than that of introverts solely on account of their higher variability and/or extent of movement. It has indeed, on a number of occasions, been shown that rate of improvement in performing the F.R.T., even using various levels of difficulty, was either the same for extraverts and introverts or, more often so, higher for extraverts (Brengelmann, 1958e; 1958f; Fig. 3.18). This statement applies only to test

scores which are unlikely to be interfered with by expressive movement. In general then, the effects of expressive movement should be assessed whenever they are likely to interfere with other test scores or conditions investigated.

CHAPTER 4

Abnormalities of Sensory Perception

G. W. GRANGER

I. INTRODUCTION

The Psychophysical Approach to Perception

IN preparing this chapter it seemed preferable to discuss a few well-investigated topics in some detail and from a definite point of view rather than attempt to say something briefly and eclectically about all aspects of the subject. The survey is restricted to *visual* perception where most of the research of interest to abnormal psychology has been carried out and, within this area, to processes which are usually classified as *sensory*.¹ The point of view which has influenced the selection of data is psychophysical. This approach to perception is not a novel one. On the contrary, it has been widely adopted in visual research for more than a century by sensory psychologists, physiologists and physicists. The psychophysical tradition was the "forerunner of the first genuinely experimental psychology" (Guilford, 1936) and it would be superfluous to mention it in a book devoted to experimental psychology were it not for the fact that a great deal of perceptual research in abnormal psychology has developed along quite different lines, under the influence of the mental-test movement, psychiatry and psychoanalysis. In consequence, the point of view adopted in this chapter may be unfamiliar to some clinical psychologists and needs to be stated explicitly and justified.

Developing as it did out of experimental physiology and the quantitative methods of the natural sciences, the psychophysical tradition is characterized by a search for quantitative laws (functional relations) between stimulus and response variables. In contrast to the psychometric approach to perception which (influenced no doubt by practical problems of selection and the need for diagnostic devices) has concerned itself with the amount of statistical association be-

tween individual differences in performance on perceptual *tests* under what may be termed "field" conditions, psychophysics has been primarily concerned with the *form* of the relationship between relatively isolated stimulus and response variables under controlled experimental conditions.

Before functional relations can be established between stimulus and response it is obviously necessary first to specify the stimulus. In the case of sensory research on vision this means specifying the quality and quantity of light entering the eye, its distribution in the field of view, duration, and similar characteristics. Next we have to specify relevant conditions of the organism, such as the state of light or dark adaptation, pupil size, retinal area stimulated, etc., and finally the response, verbal or otherwise.

The assumptions of a behaviourist¹ approach to perception have been expressed by Graham in the following general relation: $R = f(a, b, c, \dots n \dots t \dots x, y, z)$, in which R refers to response, the first letters of the alphabet to properly specified aspects of stimuli, the last letters to properly specified conditions of the organism ("physiological and inferred, including the effects of instruction stimuli" (Graham, 1952, 62)), n to number of presentations and t to time. (Graham points out that the various terms are not always independent of one another.) In the classical type of psychophysical experiment we are interested specifically in R as a function of a single attribute of the stimulus, say intensity, all other conditions being held constant as far as possible. Graham's general equation then becomes $R = f(a)$.

To meet the requirements of the experimental programme implied by this formulation a great deal of research effort has been devoted to problems of photometry, colorimetry and applied optics, and to

¹ No rigid distinction is made in this chapter between sensation and perception for at the present time there seems to be no satisfactory basis, either behavioural or physiological for making such a distinction (cf. Graham, 1951; Gibson, 1948).

¹ In spite of the beliefs of some of the early psychophysicists that they were dealing with stimulus-sensation relations, the data of psychophysical experiments seem necessarily to be behavioural data.

the development of appropriate experimental techniques. Good examples of these techniques are Hecht and Shlaer's (1938) "fixation-and-flash" method for determining the absolute light threshold and dark adaptation, and Wright's (1946) binocular matching technique.

As a result of this emphasis on problems of specification and technique and the formulation of experimental problems in terms of functional relationships there now exists a body of well-established quantitative data and generalizations concerning some of the basic visual processes such as adaptation and intensity discrimination. These psychophysical functions, which define laws of perception, provide a firm experimental basis for investigating the effects of various abnormal conditions. It will be a thesis of this chapter that *such effects can best be assessed by recording their influence on the parameters of the basic psychophysical functions for the visual reception process.*

If we are to start from reproducible quantitative data it is difficult to see how there could be any other basis for discussing abnormalities of perception. Although in many cases suggestive for further research, data from clinical tests are not sufficiently reproducible or analytic to provide a basis for quantifying the effects of abnormal conditions. With few exceptions (as for instance in the case of Hecht and Mandelbaum's (1939) study of the relation between vitamin A deficiency and dark adaptation) where perceptual tests have been developed from previous psychophysical research, these data consist largely of correlation coefficients and analyses of variance between isolated and, from the viewpoint of sensory research, often quite arbitrary, test scores obtained under complex and inadequately controlled conditions.¹ With the reasons for the curious bifurcated development which mental measurement has undergone we cannot be concerned here (see Guilford, 1936, for a detailed discussion). Whatever the causes, the

fact remains that perceptual research using psychometric methods has been pursued independently of that in psychophysics and often without regard to the basic variables of visual experiments and the techniques that have been developed to handle them. This applies particularly to much of the research arising from the so-called "new look" movement in perception which has put so much emphasis on the role of personality factors, and to a great deal of perceptual research in clinical psychology directed towards the development of diagnostic tests.

In spite of their limitations, however, data from psychometric studies have been included in this chapter whenever they seemed to fulfil minimum requirements of specification and reproducibility. Data from so-called "projective" tests, like the Rorschach, have, on the other hand, been entirely omitted. The aims, methods and universe of discourse of advocates of these techniques are at present so far removed from those of experimental psychology that it was felt inappropriate to discuss such data in a book of this kind. The fact that experimental studies of after-images, contour and contrast effects, figural after-effects, apparent movement and other well-known perceptual phenomena have also been omitted should not be taken to imply that they have been omitted for the same reasons as have psychometric and projective test data. Such studies are of undoubted importance but, so far, experimental work in these areas has tended to be demonstrational rather than analytic, and adequate measuring techniques are in certain cases only just beginning to be developed (e.g. for measuring brightness changes in after-images (Padgham, 1953; 1957) and very few functional relations have been well established (see, for instance, Graham's (1951) excellent review of *Visual Perception*). In a chapter where considerable selection of topics has had to be made it seemed preferable to deal as far as possible with areas of perception in which our knowledge is most certain and where quantification is most highly developed.

The psychophysical point of view which has determined the choice of perceptual functions has also influenced the selection of abnormal conditions. Considerable space has been devoted to physiological stresses such as anoxia and very little indeed to functional psychiatric disorders, such as neuroses. There are several reasons for this. First, experiments on physiological stresses have been concerned with functional relationships whereas studies of psychiatric patients have, with few exceptions, dealt only with rather arbitrary scores obtained from perceptual tests. Second, stimulus conditions have been carefully specified and controlled in studies of stresses whereas specification is much less precise in much of the psychiatric research. Third, in contrast to physiological stresses, functional disorders are, from an

¹ In pointing out this limitation there is no implication that the scores from such tests are worthless; only that the tests must be analysed experimentally before their sensory or perceptual significance can be known. Tests of "night-vision," such as the Livingston Rotating Hexagon test (Livingston and Bolton, 1943) have been shown to be of considerable value in practical situations even though it is not known to what extent the scores on these tests are determined by the absolute light threshold, scotopic acuity, pupil size, etc. Critics of some of the psychometric and factor-analytic work on perceptual tests have not always been clear on this point and have evaluated test scores as if they were intended to measure specific psychophysical functions when the intention of the test constructor was something quite different, viz. to assess certain operationally defined capacities (probably involving sensory, motor and other components) in an attempt to differentiate clinical groups, make predictions in personnel selection or measure traits of personality. Some of the psychologists who have adopted a psychometric and factor-analytic approach to perception have been well aware of the limitations of their method and emphasized the need for experimental analysis to reveal functional relationships (e.g. Thurstone, 1944; Eysenck, 1953).

experimental point of view, at present very difficult to specify and reproduce. Finally, reviews of the literature on neuroses and "functional" psychoses are already available elsewhere (Granger, 1953; Zubin *et al.*, 1957). To devote space to data which have no firm experimental basis seemed inappropriate in a handbook of *experimental* abnormal psychology.¹

In spite of the inadequacy of the psychiatric data some readers may feel that by omitting them the author has left out almost the whole of abnormal psychology for there has been a tendency in some quarters to equate abnormal psychology with the study of psychological abnormalities in functional mental disorders. If, however, our approach to abnormal psychology is, as in this book, based on the psychological functions themselves rather than on psychiatric categories this definition is at once seen to be too narrow, for the so-called functional disorders represent only a fraction of the total number of abnormal conditions which affect perception. In addition to physiological stresses and drugs there are numerous organic conditions such as metabolic and cardiovascular disorders which must also be considered. From the practical viewpoint of experimental work on perception these organic conditions are of greater immediate interest for they can be specified more accurately.

It will be obvious to the reader that, apart from purely practical reasons of the type just considered, the psychophysical approach to perception can show no particular preference for one type of abnormal condition rather than another and makes no rigid distinction between "normal" and "abnormal" conditions. Although from certain points of view it may be useful to distinguish between "normal" and "abnormal"—or, as some sensory physiologists prefer to call them, "special" conditions (cf. Wald, 1954)—this distinction is of no fundamental importance. The chief concern of the psychophysicist is that the basic variables should be identified and specified as conditions of the organism in Graham's equation (page 108) and their quantitative effect assessed in terms of specific perceptual functions. This requirement applies also, of course, to the various personality factors about which so much has been written in recent years (Blake and Ramsey, 1951).

Psychophysics and Physiology

The psychophysical approach to the measurement of visual functions is associated in this chapter with a

physiological point of view towards their analysis. This association between psychophysics and physiology is a traditional one which stems from their common origin in the physical sciences. The physiological method is well known but needs to be stated explicitly and justified for the same reason that it was earlier felt necessary to state the psychophysical approach to perception.

From the physiological point of view the visual system is considered to function as a physical mechanism, the eye being regarded as a complicated set of instruments for the detection of light stimuli. Stimulation of the eye by light causes a series of reactions in the subject's nervous system which spread from the photoreceptors to afferent nerve fibres, to the central system and then to effector systems (Pirenne, 1948). It is in this general way that physiology considers the chain of events in an experiment on the visual threshold in which a subject, say, presses a key to signal the detection of the light stimulus.

Although the psychophysicist may not be immediately concerned with the detailed analysis of the events occurring between stimulus and response, the physiological formulation of perceptual problems is essentially similar to the psychophysical. In both cases the subject's response is regarded as a neuromuscular reaction and in both cases an attempt is made to avoid the use of mentalistic concepts of sensation such as "seeing" and "vision." Where these terms are employed, they are used (or should be used) for convenience, as a mere manner of speech. In strict accordance with physiological method they should be replaced by more cumbersome phrases such as the "reaction of photoreceptors and nervous system to certain electro-magnetic radiations," as Pirenne (1948) has pointed out in a valuable discussion of the physiological point of view. This type of formulation may seem to some readers arbitrary or pedantic but it arises from a real desire to define perceptual problems in terms of the actual observables of visual experiments, to adopt a consistent attitude to all aspects of the S-R reaction, and to integrate perceptual research with physical science.

Although visual physiology concedes that the subject's response in a perceptual experiment is the outcome of a complicated series of reactions involving receptor, adjustor and effector mechanisms, it has in practice put a great deal of emphasis on peripheral receptor processes for it has always seemed a primary problem to ask how the quantitative characteristics of vision are limited and determined by the peripheral (and more accessible) reactions which occur when the eye is stimulated by light. In an extreme form the physiological point of view is exemplified particularly well by the work of Hecht and his associates, which provides much of the "normal" data against which

¹ Reference to these reviews, both of which have been written from a very different viewpoint from that of this chapter, reveals a mass of interesting observations and speculations concerning perceptual differences between normal and psychiatric groups that undoubtedly merit experimental study, but a paucity of reliable and definitive data.

the effects of abnormal conditions have been considered in this chapter.

Discussing the nature of the visual process in his 1937 Harvey Lecture, Hecht had the following to say—

A process such as vision in man represents a complicated series of events. It is not only the photoreceptor process itself which takes place in the outer end organs; but the nerve impulses which come from them, and which, when joined by other impulses, then pass through the various pathways to be transmitted, amplified, and perhaps altered until the final results at the cortex are achieved. Nor is the photosensory system of other animals much simpler. The receptor process is there, impulses are involved, ganglia have to be passed, and reflexes have to be initiated.

Since all these elements enter into the end result they surely influence its characteristics to some extent. The question is to what extent? And the answer can be secured only by experiment. Our own idea has been that no matter what enters in the chain of events, the ultimate place of origin of the impulses which pass along the optic tracts is in the initial action of light on the receptor cells in the sense organ. Therefore, for a number of years we have measured the different functions of vision and photoreception in man and other animals to ascertain how their quantitative properties depend on the characteristics of these very first reactions which must take place between light and the sensitive elements (Hecht, 1938, p. 37).

Elsewhere Hecht wrote—

The advantage of dealing with this first process is that it is photochemical, and that the properties of photochemical systems have been much studied and clearly formulated (Hecht, 1936, p. 17).

Although Hecht's extreme photochemical point of view has met with a good deal of opposition, most research workers in the physiology of vision have adopted a peripheralist method of study. While admitting that visual behaviour must be dependent in part upon processes occurring at the higher levels of the visual system it has seemed economical and necessary to first account for as many data as possible in terms of retinal events. In practice this approach has been dictated largely by the availability of experimental techniques and the relative ease with which peripheral events can be studied, as compared to more central processes.

In spite of its acceptance by visual physiologists and physicists, this point of view has had relatively few adherents among psychologists working in the field of perception. Instead of starting their analyses of visual processes in the periphery (i.e. with the stimulus and receptor mechanism) many psychologists, particularly of the Gestalt school, have either completely ignored the contribution of the periphery or made only passing

and inadequate reference to it. This tendency, already apparent in much of the research on the general psychology of perception (see, for instance, Vernon's book, *A Further Study of Visual Perception* (Vernon, 1952)) and Tansley's (1953) critical review, made from a physiological viewpoint), has recently become very pronounced in perceptual research in differential psychology, personality study and clinical psychology. In their desire to reveal personality traits and to devise diagnostic tests of "central" disorders psychologists in these areas have devoted very little attention to peripheral events.

The limitations of what some sensory physiologists have (incorrectly) termed a "purely psychological approach," which starts by postulating hypothetical central mechanisms, and the fruitfulness of the peripheral method of analysis are brought out particularly well by some of the recent researches on problems of seeing at low illuminations. Contrary to what has often been supposed, a large part of the observed fluctuation in visual response at or near the absolute threshold of vision is due not to fluctuations in the subject's "attention," "central fatigue," or "inhibition" (see Guilford (1927) for references), but to unavoidable physical fluctuations in the light stimulus itself. At low illuminations no light source, however well controlled, is perfectly steady. The number of light quanta it emits fluctuates statistically from moment to moment about a mean value, as does the number of light quanta absorbed by the visual cells. Although biological variation may also be present it can only be assessed in relation to the physical variation; under certain conditions it is the physical variation which appears to dominate the S-R relationship (Hecht, Schlaer and Pirenne, 1942; Pirenne, 1956).

The discovery of regularities in visual behaviour due to the quantum nature of light (a direct outcome of the consistent application of the peripheralist method (Hecht, Schlaer, and Pirenne, 1942)) has implications not only for research on "simple" functions such as the absolute threshold but also for detail perception. Pirenne, Marriott and O'Doherty (1957) have shown, for instance, that under certain experimental conditions a close relationship must, for purely physical reasons, be expected to exist between the absolute light threshold and perception of detail not only in typical acuity objects such as Landolt Cs but also in complex reproductions of pictures. The relatively high positive correlation which Pirenne *et al.* were able to demonstrate failed to reveal itself in some of the more "psychologically-oriented" investigations (see, for instance, Craik and Vernon (1942)) due, apparently, to an omission on the part of investigators to give adequate attention to the specification, control and theoretical significance of peripheral variables in

the visual process. In view of their results Pirenne *et al.* rightly (but perhaps a little too modestly!) point out that some of the rigid distinctions drawn between *sensory acuity* and *perceptual efficiency*, and conclusions about the allegedly poor predictive value of sensory threshold measurements as indicators of night visual efficiency in various wartime studies, "may not be quite as safely established as is often believed."

In spite of severe criticisms of the psychophysical and physiological approach to perception by some proponents of the personality via perception movement, clinical psychologists, and psychoanalysts (*see* for instance, Bruner and Krech, 1949), there seems to be nothing in recent research which invalidates this point of view. On the contrary, its proven usefulness in analysing normal perceptual processes encourages its application to abnormal conditions.

Rejection of this well-tried method may have been due in part to a misunderstanding of the claims of those who have used it. Contrary to what has often been supposed, even such extreme peripheralists as the photochemical theorists have never denied that visual thresholds can be influenced by the state of the central nervous system. As careful reading of the quotation from Hecht will show, there is plenty of scope in his scheme for all sorts of central influences and interactions to be considered, including individual variations in C.N.S. excitability which are the special object of study of personality psychologists.¹ That these central sources of variation must be measured and analysed under both normal and abnormal conditions before we can claim to have a complete understanding of visual mechanisms would be readily admitted by the photochemist and sensory physiologist.

Far from denying their influence, photochemical theorists such as Hecht and Wald have made some of the most precise measurements and analyses of these central factors under conditions of physiological stresses such as anoxia and insulin hypoglycaemia. These and similar studies by McFarland and his associates provide the framework for most of the discussion of abnormal conditions in this chapter not only because they are based on precise measurements

of well-defined psychophysical functions (*see* page 109) but also because they are considered to be of more fundamental importance to psychophysiology than are studies of specific clinical disorders. Their importance derives from three features of the experiments. First, they deal with basic discriminatory reactions of the organism's receptor mechanisms and may be expected to have implications for a variety of other perceptual functions. Second, the stresses which have been investigated cause disturbances of basic metabolic processes and neural effects similar to those observed in clinical disorders of several different bodily systems. Third, in contrast to much of the research in the clinical literature, the perceptual effects of these stresses have been systematically analysed within a framework of quantitative physiological theory.

Arrangement of Chapter: Content and Treatment

The chapter is arranged in six parts. Following this introduction, Part II deals with *Discrimination* and Part III with *Adaptation*, both basic properties of receptor systems. Part II is further subdivided into two sections, one dealing with the discrimination of intensity (brightness discrimination)¹ and spatial extent (visual acuity), the other with an aspect of temporal discrimination (critical flicker frequency). In discussing discrimination particular attention is given to the way in which it varies as a function of intensity of illumination for not only are the functional relationships well-established for all three aspects of discrimination, but quantitative theory has been particularly well developed in this area of research. Part III is entirely concerned with dark adaptation because most of the work relevant to abnormal psychology has been done on this aspect of adaptation.

Part IV of the chapter deals with a psychophysical and physiological analysis of the effects of the various abnormal conditions, while Parts V and VI deal with the implications of this analysis for other abnormal conditions and other perceptual functions.

Each visual function is discussed according to the following scheme: first, the basic psychophysical data are reviewed; second, theories and facts concerning physiological mechanism are discussed and, third, the effects of physiological stresses, drugs and other abnormal conditions are considered. Even

¹ In saying this the author has in mind a limited number of personality studies in which there is some reference, although often indirect, to neurophysiology, such as Eysenck's (1957) experiments on stimulant and depressant drugs. Most of the research on personality and perception is undertaken from a point of view so different from that of sensory physiology that it cannot be related to physiological research on vision. For a valuable discussion of the relation between physiological psychology and personality study, the reader is referred to Eysenck (1957). One of the major tasks of personality study, as Eysenck conceives it, is to analyse individual variation in factors which appear as constants in the physiological psychologist's equations. This point of view may be compared with that stated on page 109, namely, that the effect of abnormal conditions, variations in the state of the C.N.S., etc., can best be assessed by recording their influence on the parameters of psychophysical equations for the receptor process.

¹ Although it seemed preferable in a chapter of this kind to use these terms which are well known in the psychological literature, the thresholds to which they refer should, more properly, be designated as *luminance difference thresholds*, the experimental measurements referring to photometric quantities. It should be noted that some of the photometric terms and units used by investigators cited in this chapter are no longer in common use. For further information the reader is referred to the tables of conversion factors and discussion of photometric concepts given in the *Handbook of Experimental Psychology*, Ed. S. S. Stevens (John Wiley and Sons, Inc., New York, 1951).

though the chapter has been restricted to a few aspects of visual function, the psychophysical and physiological sections cover but a small fragment of the very extensive and specialized literature on vision. In selecting psychophysical material for inclusion the author has emphasized those features of the experimental data that seemed essential for evaluating the effects of the various abnormal conditions without burdening the reader with a detailed review of the literature. Considerations of a similar kind have determined the selection of experimental and theoretical material for the physiological section.

The particular choice and treatment of topics may appear, particularly to readers who are familiar with recent experimental and theoretical developments in visual research arising from the application of quantum and information theories, to give an inadequate and outmoded view of the psychophysiology of vision. In particular, it may appear that undue prominence has been given to the experimental and theoretical contributions of the late Selig Hecht and his associates. Some of the author's reasons for devoting so much space to Hecht's psychophysical work derive quite simply from the fact that Hecht provided what is probably the best critical synthesis of the early and basic psychophysical data on the functions dealt with in this chapter and, with his associates, verified, extended and analysed the data under rigorously-

controlled conditions. Although recent measurements present a more complicated picture than appears from Hecht's analyses, these hardly affect those features of the data with which this review is concerned. The justification for dealing with Hecht's photochemical theory in some detail rests in part on the fact that Hecht provided a systematic quantitative treatment of visual data which served as a framework for the design and interpretation of some of the best researches so far undertaken on the effects of abnormal conditions. For this reason alone a fairly detailed discussion of his theory seemed necessary for the proper understanding and evaluation of the experiments.

To avoid giving the impression, which the sight of photochemical equations might convey, that the author is prejudiced in favour of an archaic theory (to which some of its harshest critics have applied the term "classical!"), he hastens to add and emphasize that the now widely-recognized limitations of simple photochemical theories of vision are accepted and discussed. What is advocated in this chapter is not the adoption of a photochemical (or, for that matter, any other) theory of vision but of the quantitative physiological method as exemplified by Hecht's researches, for it is considered that these provide a paradigm for the experimental investigation of abnormalities of sensory perception.

II. DISCRIMINATION

Brightness Discrimination and Visual Acuity

PSYCHOPHYSICAL DATA

(a) Brightness Discrimination

Early research by Steinheil (1837), Weber (1834) and others (*see* Hecht (1924c) for review) showed that the discrimination of intensity differences is relative and depends on the prevailing intensity. According to the early data, if I and $I + \Delta I$ are two intensities that can just be discriminated, the ratio $\Delta I/I$ is roughly constant. On the basis of inadequate measurements Fechner (1860) put forward the generalization that this fraction was constant (the Weber-Fechner law). This was shown to be invalid by Aubert (1865) whose results have been confirmed repeatedly by other workers (Hecht, 1924c, 1935).

The steady decrease in $\Delta I/I$ with increasing I is clearly shown in Fig. 4.1, based on Hecht and Wald's (1934) data for the eye of *Drosophila*. The curve drawn through the experimental points has the form

$$\Delta I/I = c(1 + 1/KI) \quad (1)$$

where c is a constant determining the position of the curve on the ordinate and K the constant determining

5—(B.-E.8)

its position on the abscissa. Owing to the method of plotting the data on a double logarithmic grid their form and that of the curve are independent of the constants. Typical measurements for the bee by Wolf

FIG. 4.1. INTENSITY DISCRIMINATION OF *Drosophila*
(Hecht and Wald, 1934; after Hecht, 1935)

FIG. 4.2 INTENSITY DISCRIMINATION OF THE HONEY BEE

(Wolf, 1933a, b)

The filled circles are the data from the first paper; the open circles from the second. The numbers attached to the curves are the visual acuities multiplied by 1,000 and are inversely proportional to the size of the stripes used for the measurements.

(After Hecht, 1935)

FIG. 4.3. INTENSITY DISCRIMINATION OF THE HUMAN EYE

Blanchard's (1918) measurements are the open circles; those of Lowry (1931) are the filled-in circles and have been raised 0.15 log unit along the ordinates to bring them into continuity with Blanchard's data.

(After Hecht, 1935)

(1933) are shown in Fig. 4.2. In this case the curve represents a somewhat different equation, though similar in form to equation (1), viz.

$$\Delta I/I = c[1 + 1/(KI)^{\frac{1}{2}}]^2 \quad (2)$$

The same equation fits Hecht's (1924a) data for the clam *Mya*.

Whereas the relationship in the above instances is clearly a single continuous function, Aubert's (1865) data on the human eye and the later measurements of Blanchard (1918) and Lowry (1931) (obtained with "white" light) break into two parts, suggesting separate receptor systems. Fig. 4.3 shows the two sets of data plotted on the same graph. The high intensity portion of the data can be fitted by equation (2) while the curve for the low intensity portion is from equation (1), although either equation is satisfactory.

The dichotomy already apparent in the data of Fig. 4.3 obtained with "white" light, suggesting rod and

cone function, has been brought out in other ways, by making use of light from different parts of the spectrum and employing different retinal locations. The early data of Koenig and Brodhun (1889) were obtained using red (670 $m\mu$), orange (605 $m\mu$) and yellow (575 $m\mu$) light and show a single continuous function for the red and duplex curves for the orange and yellow. Fig. 4.4 is based on the more recent and reliable measurements of Hecht, Peskin and Patt (1938) for red, orange, yellow, green and blue light.

FIG. 4.4. HUMAN INTENSITY DISCRIMINATION FOR THE RED, ORANGE, YELLOW AND BLUE PARTS OF THE SPECTRUM

The labelling on the ordinate applies to the data for yellow (575 $m\mu$). The orange and red curves have been raised 0.5 and 1.0 log unit, respectively, and those for green and blue have been lowered 0.5 and 1.0 log unit, respectively.

(Hecht, Peskin and Patt, 1938)

Fig. 4.5 shows the relation between $\log \Delta I/I$ and $\log I$ for different retinal areas, as determined by Steinhardt (1936). The upper data were obtained with a field 51' in diameter falling largely within the rod-free area of the fovea and indicate a single function while the lower data, obtained from an area containing both rods and cones, show an inflexion point. Other data of Steinhardt's indicate a duplex curve when the test area is larger than 2° and a single curve similar to the curve for red light in Fig. 4.4 when small foveal fields are used (see Fig. 4.6.) Results essentially similar to those of Steinhardt have been obtained by Crozier and Holway (1939b) and

Holway and Hurvich (1938). The curves drawn through the data of Figs. 4.4, 4.5 and 4.6 are the same as those drawn through the measurements of Figs. 4.2 and 4.3. All the "cone" data are described by

FIG. 4.5. INTENSITY DISCRIMINATION WITH DIFFERENT RETINAL AREAS, AND WITH WHITE LIGHT

(Steinhardt, 1936)

The upper data are with a field 51' in diameter; the lower with a field 3' 44' in diameter

(After Hecht, 1935)

FIG. 4.6. INTENSITY DISCRIMINATION FOR THE HUMAN EYE AS INFLUENCED BY ILLUMINATION AND SIZE OF FIELD

(Steinhardt, 1936)

equation (2) while the more limited "rod" data can be fitted almost equally well by either equation.

The data of intensity discrimination are considerably more extensive than those that have been presented here and in any complete treatment of the topic other variables such as duration (Graham and Kemp, 1938), spatial separation of comparison areas

(Smith, 1936), state of adaptation of the eye (Wright, 1935), etc., would need to be considered. For the present purpose, however, the data are sufficient and there appears to be nothing in the psychophysical literature that seriously invalidates the general form of the relation between intensity discrimination and illumination, which results from Hecht's (1934*a*, 1937)

(1897) investigation was so thorough that his data have become classical. They show that the relationship between acuity and the logarithm of the intensity is sigmoid (*see* Fig. 4.7). The general form of this relation has since been confirmed repeatedly for the human eye (Löhner, 1912; Rice, 1912; Roelofs and Zeeman, 1919; Ferree and Rand, 1923; Lythgoe,

FIG. 4.7. RELATION BETWEEN HUMAN VISUAL ACUITY AND ILLUMINATION IN WHITE LIGHT

(Koenig's (1897) data, replotted by Hecht.)

The original intensities have been multiplied by 0.072 to convert them into mL.

(After Hecht, 1928)

analyses. The basic relation through the receptor systems of both rods and cones appears to be relatively unaffected by variation in area, duration, etc., the effect of variation in these factors being merely to alter the extraneous constants of this relation, as in Fig. 4.6.

(b) Visual Acuity

Visual acuity may be defined as "the reciprocal of the angular distance which must separate two contours in order that they may be recognized as discrete," the unit of separation being a minute of arc (Hecht, 1928). Like brightness discrimination, acuity is dependent among other things upon the intensity of illumination. Uthoff (1886, 1890) was the first to study this relationship over a wide range but Koenig's

1932; Wilcox, 1932, and others) and for the eyes of other animals (e.g. Hecht and Wolf, 1929; Hecht and Wald, 1934; Clark, 1935). Studies on the influence of spatial effects (e.g. Brown, 1946) and stimulus duration (Niven and Brown, 1944) have given results essentially similar to those for intensity discrimination, the basic form of the relation remaining unaffected.

The later studies have demonstrated that several factors not controlled in the earlier work (even in Lythgoe's often-quoted 1932 study) have an important influence on the results. They include pupil size, distance of the test object from the eye and the luminance and extent of the field surrounding the test object. To avoid these uncontrolled variables Shlaer (1937) designed an apparatus for presenting a test

object that could be varied continuously in size over a range of about 1:100 at a fixed distance of one metre from the eye. This test object appeared in the centre of a 30° field and was observed through a 2-mm diameter artificial pupil. Means were provided for varying the illumination over a wide range (1:10¹⁰) in steps of about 0.3 log unit.

Two types of test object were used, a Landolt C and a grating. Data for both test objects show a break at a visual acuity of 0.15. Typical results are shown in Fig. 4.8 for the Landolt C. The curves drawn through the data are the same as those drawn through the similar data for intensity discrimination (Hecht, 1935).

As in the case of intensity discrimination, the dichotomy of acuity data becomes clearly apparent in

FIG. 4.8. HUMAN VISUAL ACUITY AND ILLUMINATION FOR WHITE LIGHT, USING THE MOST SENSITIVE PORTION OF THE RETINA (Shlaer, 1937)

a double log plot and when colour and retinal location are varied. The effect of spectral variation was already apparent in Koenig's data which break into two parts when blue, green or white light was used but give a single function for red. Fig. 4.9 is based on the more accurate measurements of Shlaer, Smith and Chase (1942).

Pirenne, Marriott and O'Doherty (1957) have recently extended Shlaer's (1937) curves to include lower luminance levels. They measured the luminance levels required to resolve black Landolt Cs presented against a large circular "white" field subtending 47° at the eye. Eight test objects were used ranging between acuities of 1/3 and 1/295. Subjects were first dark adapted for half an hour and after their absolute thresholds had been measured the 47° field was exposed and the thresholds of visibility of the various Landolt Cs were determined binocularly using the natural pupil, one after the other, beginning with the largest C. A given C test object was presented in four positions with the gap facing up, down, right or left, in random succession, and the field luminance adjusted

in steps of 0.1 log unit until the subject judged correctly the position three times out of four trials. In Fig. 4.10 the results of this investigation are combined with those of Shlaer in the higher acuity range, in a double log plot. The horizontal broken line at acuity 1/3 indicates the upper limit of Pirenne, Marriott and O'Doherty's measurements.

FIG. 4.9. HUMAN VISUAL ACUITY IN RED AND BLUE LIGHT (Shlaer, Smith and Chase, 1942)

FIG. 4.10. DIAGRAM SHOWING THE GENERAL VARIATION OF VISUAL ACUITY WITH FIELD LUMINANCE, USING A LANDOLT C TEST OBJECT (Pirenne, Marriott and O'Doherty, 1957)

The dotted line represents an extension of Shlaer's curve, based on Pirenne, Marriott and O'Doherty's data. Agreement between the two sets of data is very satisfactory over the range where they overlap (individual experimental points are shown in Fig. 1 of a paper by Pirenne and Denton, 1952). When pupil variation is taken into account agreement is even closer.

Some indication of the nature and extent of individual variation in acuity measurements at low

luminance levels can be obtained from Fig. 4.11 which shows the mean log-acuity/log-luminance curve for twenty-two subjects. The curves on either side join the experimental values corresponding to twice the standard deviations. These vary between 0.142 and 0.240 log unit and are of about the same order of magnitude as the standard deviation for the absolute threshold; only one out of seven standard deviations

FIG. 4.11. ACUITY *v.* FIELD LUMINANCE

The main curves join the mean experimental values of twenty-two subjects for the C thresholds; the curves on either side join the values between which fall the results for the bulk of the population as explained in the text.

(Modified from Pirenne, Marriott and O'Doherty, 1957)

differed significantly from the standard deviation of the absolute threshold.

A particularly interesting feature of Pirenne, Marriott and O'Doherty's data is the general similarity in shape of the individual log-acuity/log-luminance curves at the lower acuity levels. The chief difference between individuals is in the position of their curves along the intensity axis, as illustrated by the three curves of Fig. 4.12. Correlations between luminance thresholds for the Landolt Cs and the absolute threshold ranged from 0.705 to 0.927 ($p < 0.001$).

PHYSIOLOGICAL DATA AND THEORIES

(a) Hecht's Photochemical Theory

(i) *The stationary state.* Hecht's (1937)¹ theoretical treatment of the data of brightness discrimination and

¹ Although Hecht's name is usually associated with photochemical theory, Pütter (1918) and Lasareff (1928) also contributed a number of ideas.

visual acuity is based on three simple chemical ideas concerning the photoreceptor process. First, there has to be a sensitive substance which absorbs the incident light and is changed by it into one or more active products. Second, a supply of this photosensitive material must be maintained if the process is to continue. These two processes Hecht terms the *primary light* and *primary dark* reactions, respectively. Third, the active products of the primary light reaction must do something the end result of which is the initiation of an impulse from the receptor cell. This is termed the *secondary dark reaction*.

Hecht then goes on to consider the properties of the *simplest* photochemical system which would correspond to the primary light and dark reactions. "Consider a photosensitive substance *S* whose total initial concentration is *a*. Let light of intensity *I* shine on it, and as a result let there be produced the photoproducts *P*, *A*, etc., whose concentrations at the moment *t* is given by *x*. The rate at which this primary light reaction $S \rightarrow P + A$ goes will be proportional to the intensity and to the concentration

FIG. 4.12. VARIATION OF ACUITY WITH LUMINANCE

Individual C threshold values for three subjects

(Modified from Pirenne, Marriott and O'Doherty, 1957)

($a - x$) of sensitive material" (Hecht, 1938). This rate may be written—

$$dx/dt = k_1 I(a - x)^m \quad (3)$$

where k_1 is the combined absorption and velocity constant and m is an integral exponent which chemists term the order of the reaction, and may be 1, 2, etc.

Further suppose that the sensitive material *S* can

be regenerated (by the combination of some of the photoproducts, P , A , etc., with additional materials like vitamin A supplied by the retina). The velocity of this primary dark reaction $S \leftarrow P + A$ will be proportional to the concentrations x of the photoproducts and becomes—

$$-dx/dt = k_2 x^n \quad (4)$$

where k_2 is a velocity constant and n the order of the reaction.

When this system is steadily exposed to light (corresponding to light adaptation to a given intensity), the velocities of the two reactions become equal and a *photostationary state* is reached. Setting equation (3) equal to (4) and solving for I , we get—

$$KI = x^n/(a - x)^m \quad (5)$$

where $K = k_1/k_2$, which represents the relations between intensity and concentrations of photosensitive substance and photoproducts at the stationary state of the simple three-component system—

In presenting this formulation Hecht emphasized that it is “too simple to correspond to what the photoreceptor process probably is” but at the same time brightness discrimination, visual acuity and various other visual functions all behave “as if they were controlled by just such a simple system as represented by the stationary state” (Hecht, 1938, p. 58).

(ii) *Brightness discrimination.* Having derived the stationary state equation Hecht considered the problem of brightness discrimination in the following way. The photochemical change produced by the intensity increment ΔI which can just be recognized when the eye is adapted to I is —

$$dx/dt = k_1 \Delta I (a - x)^m \quad (6)$$

Assume that the *j.n.d.* in intensity is perceived when the number of impulses leaving the photoreceptor system is increased by a constant amount c' . This makes equation (6) equal to c' and gives $\Delta I = c'/k_1(a - x)^m$. Dividing this value of ΔI by the value of I obtained by solving equation (5) we get—

$$\Delta I/I = c'/k_2 x^n \quad (7)$$

i.e. “intensity discrimination varies as some power of the concentration of photoproducts present at the stationary state.”

x can be eliminated and comparison made between this general derivation and experimental data of $\Delta I/I$ against I only in terms of equation (5) when m and n are given specific values. When both the

primary and light and dark reactions are monomolecular and m and $n = 1$, equation (7) becomes—

$$\Delta I/I = c(1 + 1/KI) \quad (8)$$

where $K = k_1/k_2$ and $c = c'/ak_2$. When m and $n = 2$, i.e. when both reactions are bimolecular, equation (7) becomes —

$$\Delta I/I = c[1 + (1/KI)^{\frac{1}{2}}]^2 \quad (9)$$

where $c = c'/a^2 k_2$. When plotted on a double logarithmic grid, as in Fig. 4.13, the shapes of the curves

FIG. 4.13. THE RELATION BETWEEN $\Delta I/I$ AND I IN TERMS OF THE THEORETICAL DERIVATIONS OF HECHT

Drawn on a logarithmic grid, the curves have a form which is independent of any constants in the equations, but which is determined by the values of m and n representing the order of the primary photochemical and dark reactions in the photosensory system. The numbers attached to the curves show the value of m and n in order.

(After Hecht, 1937)

of these two equations are constant and independent of any constants in the equations. Only the values of m and n determine the shapes and slopes.

The curves drawn through the “cone” data of the human eye (Figs. 4.3, 4.4, 4.5 and 4.6, as well as the similar data of Hecht, Peskin and Patt (1938), Graham and Kemp (1938), Smith (1936), Hendley (1948), Mueller (1951)¹ and others), and those of the bee (Fig. 4.2) are from equation (9) while the curve drawn through the *Drosophila* data is that of equation (8). For the “rod” data of the human eye it is more difficult to decide which particular equation applies because the data are less extensive.

(iii) *Visual acuity.* Hecht’s theoretical treatment of acuity developed in two stages, the first purely statistical and the second photochemical. According to the early formulation (Hecht, 1926, 1928) the increase in visual acuity with increasing illumination is due to the fact that individual receptors vary in sensitivity in a “statistical manner similar to that of other populations” so that more will be active at

¹ Mueller points out that a curve derived from Crozier’s (1940) theory also fits his data equally well.

higher than at lower illuminations. Thus, a given region of the retinal mosaic will become functionally (not, of course, anatomically) finer at higher intensities, maximum acuity being attained when all receptors are active.

In later publications (Hecht, 1937) Hecht attempted to show that the assumption of a statistical distribution of light detectors in the retina is a necessary consequence of the photochemical system which he used to describe brightness discrimination. Following the earlier suggestions of Helmholtz (1896) and Hartridge (1918), Hecht suggested that "Two lines are resolved as a doublet when the space between them appears of a different brightness than in the lines themselves. An object is seen as a C or an O depending on whether the circular image formed on the retina contains a break whose brightness is recognizably greater than the rest of the circle. In other words, visual acuity may be intimately related to intensity discrimination. . . ." (Hecht, 1937, p. 277). With Mintz (Hecht and Mintz, 1939) Hecht later demonstrated that visual acuity is a form of brightness discrimination in the region of the diffracted retinal image and that the critical visual acuity α is directly proportional to $\Delta I/I$.

The experimental data show that both brightness discrimination and visual acuity vary with the intensity of illumination so that if they are related in some way they might be expected to show the same relation to intensity. Visual acuity should in fact vary inversely as the fraction $\Delta I/I$ does with intensity. In terms of equation (7), visual acuity should vary as some power of the concentration of photoproducts at the steady state. Putting V (visual acuity) equal to $bI/\Delta I$ and substituting in equation (7), Hecht obtains—

$$V = cx^n \quad (10)$$

where $c = bk_2/c'$ as a lumped constant. Solving for specific values of m and n , the orders of the primary light and dark reactions, is the same as for brightness discrimination. On a double log plot the final curves are identical with those derived for brightness discrimination but are reversed in the sign of the ordinates.

(b) Alternative Theories, and Electrophysiological Data

Modifications of Hecht's theory, based on more recent information of events in the photochemical cycle have been proposed by Byram (1944, *a, b*) and Jahn (1946b). The theoretical curves which they derive certainly provide a better fit to some of the psychophysical data than do those of Hecht. Other modifications of Hecht's stationary state equation have been made by Bartlett (1942) and Bartlett and Hudson (1942) while alternative theories of a "neural"

nature have been proposed by Crozier and his associates (e.g. Crozier and Holway, 1939b). The essence of Crozier's theory, which has never been formulated explicitly, is that the sigmoid curves relating brightness discrimination and visual acuity to intensity are probability integrals in $\log I$, reflecting the statistical distribution of receptor thresholds. At the lower intensities only the most sensitive elements (rods, cones, and their associated neurones) respond whereas at high intensities all elements respond. The assumed distribution of thresholds covers between four and eight log units and the thresholds themselves vary from one element to another and from moment to moment. Crozier's theory is a general "neuro-statistical" theory of intensity discrimination which is supposed to apply to all the senses; the various senses ". . . are all controlled alike by a statistical mechanism which is an expression of the central nervous system" (Bartley, 1941, p. 44). A further example of a theory which assumes visual phenomena to be the expression of properties of hypothetical central nervous mechanisms is that of Householder (Householder, 1939; Householder and Landahl, 1945) who derives equations from assumptions about the dynamics of synaptic transmission that give a fairly satisfactory fit to some of the data of brightness discrimination.

An approach of an entirely different kind from those already considered is that of the quantum theorists. Following the successful application of quantum concepts to the absolute threshold (Hecht, Schlaer and Pirenne, 1942; Bouman and van der Velden, 1947; Baumgardt, 1950; Pirenne, 1956; see page 111), de Vries (1943), Rose (1948), Hendley (1948) and others have considered the increment threshold from the viewpoint of quantum theory. Although in the case of low field intensities it is clear that unavoidable fluctuations in the number of light quanta reaching the eye from the test area will lead to "frequency-of-seeing" curves similar to those obtained in absolute threshold experiments, it is more difficult to determine precise implications for the case where the field intensity is high or where it varies through a wide range of values. So far none of the proposed formulations has given a satisfactory account of the experimental data reviewed in the previous section. The simple formulations of Rose (1948) and de Vries (1943) can be dismissed, because they require a linear relation between $\log \Delta I/I$ and $\log I$, whereas in fact this is not observed.¹

¹ Both de Vries and Rose suggested that the eye can be compared with an ideal detector, their physical model being a photocell without any dark current. Since there is some electrophysiological evidence which suggests that the human eye does not behave like an ideal detector with no intrinsic noise, Barlow (1957) has proposed an alternative model of a photocell with dark current which provides a better fit to some of the experimental data on the increment threshold.

Mueller (1951) has posed the question as to whether quantum concepts alone can be used to "predict" or "explain" the data of intensity discrimination, or whether additional neural and photochemical mechanisms will need to be invoked. While it is too early to decide how far quantum ideas will take us, it seems highly probable that part of the change both in intensity discrimination and visual acuity¹ with variation in light intensity is due to changes in neural interaction in the retina. Results of recent electrophysiological experiments by Barlow *et al.* (1957) suggest that part of the improvement in discrimination which occurs as the intensity of illumination increases may be due to the development of *lateral inhibition*. The authors suggest that this "may be one of the mechanisms which enables full use to be made of the information contained in the light absorbed in the retina" for "it seems admirably suited to preserve information about small differences in intensity between the neighbouring regions of the visual field," the function which Rose (1948) "claimed that the visual mechanism could perform almost to the limit set by the quantal fluctuations in the light absorbed." That inhibition has an important role in sensory discrimination has been suggested also by Granit (1947, 1951, 1955) on an analogy with its function in motor activity (cf. Sherrington, 1947). Its existence has been demonstrated in the retina and optic nerve (Granit and Therman, 1934, 1935; Hartline, 1935, 1938; Granit, 1947, 1952, 1955) and its possible function in simultaneous, successive and metaccontrast, visual acuity and other aspects of discrimination has been considered by Hartline and his associates (Hartline, H. K., Wagner, H. G. and McNichol, E. F., 1952; Hartline, H. K., Wagner, H. G. and Ratcliff, F., 1956; Hartline, H. K. and Ratcliff, F., 1957), Graham and Granit (1931), Wright and Granit (1938), Granit (1947, 1955), Barlow (1953), Davson (1950), Alpern (1953), Asher (1950), Osgood (1953), Barlow *et al.* (1957), and others. A review of this literature is available elsewhere (Granger, to appear).

Until more data on "frequency-of-seeing" curves have been obtained to test the adequacy of quantum formulations, and until the electrophysiological results on retinal interaction can be related quantitatively to psychophysical data of human vision, the precise implications for visual theory of these recent

physical and physiological developments will be difficult to determine. As far as photochemical theories are concerned it now seems clear that any theory which postulates a progressive exhaustion of photo-sensitive substance in the end organs as the field intensity is increased, requires drastic modification simply because the rate of absorption of light quanta at the intensity levels in question is too slow a process (Baumgardt, 1950). Although the fraction of visual pigment which is bleached by light must be higher at higher intensities, and it may be that at any constant intensity a "stationary state" would be reached due to regeneration, it is clear that the amount of bleaching is very much smaller than Hecht supposed (cf. Rushton, 1958).

To say this is not to say that photochemical ideas should be entirely rejected; only that there are physical and physiological objections to a simple model of the type proposed by Hecht and to any *purely* photochemical theory. Although the formulation of a really adequate physiological theory remains a task for the future, it now seems certain that it will have to take account of factors both more peripheral (stimulus fluctuations) and more central (neural interaction in the retina) than did the photochemists.

In spite of the objections which can be raised against Hecht's simple scheme on physical, physiological and chemical (*see* Jahn, 1946b) grounds, from a purely psychophysical point of view this model may still have something to commend it in terms of its simplicity, and the precision with which the "stationary state" equation describes a large number of experimental data. As Hecht himself pointed out, even though complicating factors are undoubtedly present (and Graham has already considered some of these in his extension of Hecht's hypothesis to include effects of spatial and temporal interaction (e.g. Graham and Bartlett, 1940)), the equations which describe them must reduce to something like the stationary state equation in view of the precision with which it describes the data (Hecht, 1937, p. 281).

ABNORMAL CONDITIONS

Research on the effects of abnormal conditions on brightness discrimination is almost entirely confined to the study of two physiological stresses, anoxia and insulin hypoglycaemia, but these warrant detailed discussion in view of their methodological and theoretical importance.

Following the relatively uncontrolled observations of Schubert (1932) and Gellhorn (1936) that brightness discrimination was reduced by anoxia, McFarland, Halperin and Niven (1944) undertook a systematic study using Crozier's Visual Discriminometer (Crozier and Holway, 1939a). Differential thresholds were obtained for a square 1° test-field, presented against

¹ An interesting application of quantum concepts to visual acuity data is that of Pirenne (1946, 1948) and Pirenne and Denton (1952), who have shown that Hecht's hypothesis of variation in receptor sensitivity in a given retinal area is unnecessary. Because of quantum fluctuations occurring in the absorption of light by the retina these authors argue that the retinal mosaic must become functionally finer. Their theory casts doubt upon previous formulations of Lythgoe (1940) and von Buddenbrook (1940) who postulated changes in neural interaction, although it now seems (Pirenne, 1957) that in certain types of experiment interaction must be taken into account.

a large uniformly-illuminated background subtending 40° . The test-field was exposed for 0.1 sec just below a fixation point so as to appear in the centre of the larger field. Observations were made using the right eye. No artificial pupil was used as the diameter of the beam when it entered the eye was less than the minimum diameter of the eye pupil. The retinal illumination produced by the 40° field was 229 milliphotons.

the intensity (I) axis. The effect of anoxia is, apparently, greatest at the lower field intensities and becomes progressively less with increasing illumination. Data for each subject were plotted in a manner similar to that of Fig. 4.14 and the amount of displacement of each curve during anoxia determined graphically; the mean shift amounted to 0.356 log unit ($p < 0.01$). Of great interest was the fact that foveal dark adaptation curves obtained in the same

FIG. 4.14. THE EFFECT OF OXYGEN DEPRIVATION ON FOVEAL INTENSITY DISCRIMINATION

The curves are theoretical, derived from Hecht's equation, as explained in the text.

(McFarland, Halperin and Niven, 1944)

Intensity discrimination thresholds were made at increasing intensities of the larger field. Measurements were taken at a given intensity after the eye had been adapted for three to five minutes to the 40° field. Before obtaining differential thresholds subjects had previously been dark-adapted for fifteen minutes, the object of this preliminary dark adaptation being to enable comparisons to be made of the effect of anoxia on two different functions. The intensity of the test square was increased in steps of about 0.03 log unit until its outline could just be detected; at each field intensity, ten measurements were taken.

Data were obtained for nine trained subjects ranging in age between 18 and 26 years and are shown in Fig. 4.14 for one group of four subjects on the left and for the remaining five subjects on the right. The data were presented separately owing to differences in the light intensities employed. The "low oxygen" curves were obtained during a constant degree of oxygen deprivation (10.8 per cent oxygen) in a low oxygen chamber. The 100 per cent oxygen curves were obtained to demonstrate the reversibility of the effects of anoxia at the end of each experiment. The interesting feature of these data is that oxygen deprivation does not affect the *form* of the relationship between $\log \Delta I/I$ and $\log I$, but only its position on

experiment (*see* later discussion) were displaced upward along the log intensity axis by about the same amount, 0.354 log unit ($p < 0.01$). Control experiments were undertaken to see if pretended exposure to low oxygen tensions or subsequent administration of oxygen had any effect, but no changes were observed.

The curves drawn through the data of Fig. 4.14 are theoretical and are derived from Hecht's stationary state equation. McFarland, Halperin and Niven's (1944) interpretation of their data was suggested by Hecht and is essentially similar to that given in a paper by Hecht *et al.* (1946), to be discussed in Part IV.

In view of previous results which showed that glucose partially counteracted the effects of anoxia on dark adaptation (McFarland and Forbes, 1941; *see* section on dark adaptation), McFarland, Halperin and Niven (1945) decided to make a similar experiment with brightness discrimination. Under conditions similar to those of their previous experiment on anoxia they found that the ingestion of 50 g of glucose resulted in a considerable decrease in the impairment due to anoxia. At a simulated altitude of 13,800 ft glucose diminished the impairment to an amount corresponding to an altitude of only 8,000 ft in one subject, from 14,700 ft to about 11,000 ft in a second subject, and from 17,200 ft to about 9,000 ft in a third.

A further experiment by McFarland, Halperin and Niven (1946) in which they studied the effects of insulin on foveal brightness discrimination, was also based on the earlier dark adaptation studies, the apparatus being the same as that used previously. In four trained subjects, aged between 15 and 18, they found a rise in threshold if the blood sugar dropped below about 65 to 70 mg per cent (Folin Malmros method) following intravenous injections of insulin in amounts varying from 4 to 14 units. The curve relating visual thresholds to time paralleled the drop in blood sugar. Following inhalation of pure oxygen a reversal of a large part of the impairment occurred.

Plotting $\log \Delta I/I$ against $\log I$ the authors found that hypoglycaemia caused a translation of the curve along the intensity axis toward higher intensities in all three subjects. The curves for one subject are shown in Fig. 4.15. As in the case of anoxia, the effect of hypoglycaemia is greatest at low intensities and declines at the higher intensities. For all three subjects the changes observed at the low and intermediate intensities were significant statistically ($p < 0.01$); at

FIG. 4.15. THE EFFECT OF INSULIN HYPOLYCAEMIA ON THE RELATION BETWEEN INTENSITY DISCRIMINATION AND ILLUMINATION

The curves are derived from Hecht's equation, as explained in the text. (McFarland, Halperin and Niven, 1946)

the highest intensity the change was not significant in two cases and only just attained significance ($p < 0.01$) in the third.

Hecht, Hendley, Frank and Haig (1946) studied brightness discrimination with individuals breathing oxygen concentrations corresponding to seven different altitudes between sea level and 17,000 ft. Three luminance levels were used, 0.1, 0.01 and 0.001 mL, involving photopic vision only. The visual field

consisted of a large circular area subtending 27° visual angle, to which the subjects' eyes were light-adapted. In the centre of this field the illuminated image of a Landolt C could be projected for 0.2 sec. The position of the break in the circle was set by the operator and the subject's task was to discover this position by steadily increasing the luminance of the broken ring. In order to confine the study to brightness discrimination alone a large test object was used (7.5°) with a

FIG. 4.16. THE RELATION BETWEEN THE CONTRAST FRACTION $\Delta I/I$ AND THE PREVAILING I

The curves are theoretical, from Hecht's equation. The effect of altitude (or oxygen lack) is merely to translate the curve along the abscissae.

(After Hecht, Hendley, Frank and Haig, 1946)

break of 1.5° , i.e. well above the visual acuity threshold at all intensities used. Red light was used "to insure the participation of daylight vision alone even at the lowest intensity." Fig. 4.16 shows the relation between the contrast fraction $\Delta I/I$ and the prevailing I , based on the average data of eight subjects. For all three background luminances, decreasing the oxygen concentration caused an increase in the amount of contrast which could be detected. The authors considered three aspects of this visual impairment. First, deterioration in brightness discrimination was obvious at a simulated altitude of 8,000 ft and became marked at 15,000 ft where at a low luminance level the contrast had to be twice as great as at sea level before it could be recognized. Second, a given increase in altitude caused a greater impairment at higher than at lower altitudes. In going from 12,000 ft to 15,000 ft the increase in brightness difference required for recognition of contrast was twice as great as that in going from 6,000 ft to 9,000 ft. Third, although impairment occurred at all luminance levels, the effect decreased as the luminance increased. The authors made extrapolations from their data to show what would be expected at higher intensities at 1 and 10 mL and it is interesting to note that these predictions have been realized in McFarland, Halperin and Niven's

(1944) study. As in that study, the quantitative form of the relation between brightness discrimination $\Delta I/I$ and I remained the same at all oxygen concentrations. The effect of anoxia was merely to shift the curve along the $\log I$ axis.

Following the earlier, inconclusive studies of Wilmer and Berens (1918), Bagby (1921), Berger and Boje (1937) and Furuya (1937) on the effects of anoxia on visual acuity, McFarland and Halperin (1940) carried out a systematic investigation in which they studied

FIG. 4.17. THE EFFECT OF ANOXIA ON THE RELATION BETWEEN FOVEAL VISUAL ACUITY AND ILLUMINATION (McFarland and Halperin, 1940)

the relation between foveal visual acuity and illumination over a wide range of intensities, using the apparatus devised by Shlaer (1937). The test object was a black Landolt C in which the width of the line and the gap was one-fifth of the total outside diameter of the letter. It appeared in the centre of a uniformly illuminated field 30° in diameter, which was illuminated by red light (670 mμ) so as to restrict measurements to the cones. The size of the test object was continuously variable over a range of 1:100 at a fixed distance of one metre from the subject's eye, which was placed immediately behind a 2-mm diameter artificial pupil. The letter could be rotated so as to be presented in eight different meridians, 45° apart.

Starting with a gap that was too small for the subject to perceive, this was gradually increased (in steps of about 0.010 to 0.020 log unit of visual acuity) until the subject could report the meridian in which the gap was located. Data were obtained in two experiments from eleven practised subjects, two in the first experiment and nine in the second. In the first experiment measurements were taken over almost the entire range of intensities mediated by cones in normal air and when the subjects were exposed to a low oxygen mixture (10.3 per cent oxygen). After ten minutes' dark adaptation measurements were started

at low intensities in normal air. Before making observations at a given intensity the eye was light-adapted to the field for three minutes and four readings were then obtained. After making observations for five minutes the subject rested and was then given three minutes' light adaptation to the field before observing again. When the intensity range had been covered the subject rested for twenty minutes and the procedure was repeated with the low oxygen mixture. Final observations were taken to determine the effect of breathing pure oxygen.

In the second experiment data were obtained for nine subjects at two intensities, one near the low end of the range (0.144 photon) and the other near the intensity value giving maximum acuity, at 1,320 photons retinal illumination. The procedure was similar to that of the first experiment but two different oxygen concentrations were used, 14.3 per cent, corresponding to 10,000 ft and 10.3 per cent, corresponding to 18,000 ft.

Data for one of the subjects in the first experiment are shown in Fig. 4.17; each datum represents the mean of four measurements. The curve on the left shows how acuity varies with illumination in normal air, that on the right when the subject was exposed to low oxygen. Evidently anoxia causes a displacement of the entire curve to the right along the intensity axis. In view of the shape of the curve this horizontal shift results in a large decrease of acuity at low illuminations and a progressively smaller decrease as intensity is increased. McFarland and Halperin point out that this may account for the inconclusiveness of the earlier experiments which were carried out at intensity levels where changes in acuity are likely to be relatively slight. The shift along the axis amounted to 0.38 for the data illustrated and 0.66 log unit for the other subject.

The mean values for the nine subjects of the second experiment are shown in Fig. 4.18. It is unfortunate that there are so few experimental points but these were carefully determined and may be considered "sufficient to locate the theoretical curve" (i.e. for Hecht's stationary state equation). This was drawn through the "normal air" data, then translated to the right to correspond with the point representing the measurements at the low intensity, at each of the conditions of decreased oxygen tension. This curve drawn through the lower point at 10.3 per cent oxygen concentration coincides with the upper point as well. The magnitude of the horizontal displacement was 0.24 log unit for 14.3 per cent oxygen and 0.46 log unit for 10.3 per cent oxygen. Mean differences due to anoxia were statistically significant ($p < 0.01$). In view of the lack of any appreciable vertical component in the displacement of the curve, the authors conclude that: "The maximum visual acuity is not affected by

anoxia, although a higher illumination may be required to elicit it."

Using the same apparatus and procedure as that previously described (McFarland, Halperin and Niven, 1944), McFarland, Roughton, Halperin and Niven (1944) studied the combined effects of anoxia and carbon monoxide on intensity discrimination at sea level and at various simulated altitudes. Their results are of particular interest for earlier attempts to determine the least amount of carbon monoxide capable of producing impairment in behaviour had yielded no definite results with various psychological tests. They found that 5 per cent saturation of the blood with carbon monoxide depressed intensity discrimination to as great an extent as anoxia at 8,000 to 10,000 ft altitude and 15 per cent carbon monoxide saturation caused impairment equivalent to that at between 15,000 and 19,000 ft.

The sensitivity of intensity discrimination to carbon monoxide was so marked that even the effects of the small amounts of carbon monoxide absorbed from cigarette smoke could be demonstrated. After inhaling the smoke of three cigarettes the effect on sensitivity was equivalent to that of a simulated altitude of 7,500 ft (15.7 per cent oxygen). Absorption of a similar amount of carbon monoxide (4 per cent saturation) at a simulated altitude of 7,500 ft caused a combined loss of sensitivity equal to that at

FIG. 4.18. THE EFFECT OF ANOXIA ON THE RELATION BETWEEN FOVEAL VISUAL ACUITY AND ILLUMINATION

Mean values of the data for nine subjects.
(McFarland and Halperin, 1940)

10,000 to 11,000 ft. Inhaling oxygen accelerated the elimination of carbon monoxide and also produced an improvement in visual sensitivity.

One final study which it seems important to mention, even though it is based on rather limited data, was undertaken by Pirenne, Marriott and O'Doherty (1957) as part of their investigation on "night-vision

efficiency." Using the procedure previously described (page 117), acuity and "flash" thresholds were obtained from a subject who had taken part in an experiment on dehydration. Comparing his luminance thresholds after "dehydration" with normal values obtained a month later an average increase of 0.25 log unit was found. The most interesting feature

FIG. 4.19. THE EFFECT OF DEHYDRATION ON C AND "FLASH" THRESHOLDS

Open circles denote measurements made after experimental dehydration; filled-in circles denote measurements made under normal conditions.

(Pirenne, Marriott and O'Doherty, 1957)

about the results is that the whole acuity curve was displaced to higher intensities under the abnormal condition, as shown in Fig. 4.19.

Critical Flicker Frequency

PSYCHOPHYSICAL DATA

The sensation of flicker produced by regularly interrupted illumination disappears when the frequency of interruption is made sufficiently high. The frequency at which flicker can no longer be perceived is known as the *critical flicker frequency* (C.F.F.). Since Talbot undertook the first systematic experimental study of C.F.F. in 1834 an extensive literature has developed dealing with the basic psychophysical relationships. Talbot himself found that when the subjective fusion point was reached the sensation of brightness evoked is proportional to the luminance and duration, indicated by the ratio of the light:dark interval in the cycle (light-dark ratio or L.D.R.). Plateau (1835) confirmed and extended Talbot's findings and the result of their work is embodied in the Talbot-Plateau law, which appears to be perfectly exact provided, of course, fusion is obtained.

The most basic factor which determines C.F.F. is

the intensity of illumination. This dependence was recognized by Plateau but it was Ferry (1892) who first proposed the formulation that C.F.F. varies directly with the logarithm of the intensity and Porter (1902) who made the first adequate measurements over a sufficiently wide range of intensities. The validity of the Ferry-Porter law (which is a variation of the Weber-Fechner law) has since been confirmed over a wide range of intensities by Kennelly and

FIG. 4.20 THE RELATION BETWEEN CRITICAL FREQUENCY AND LOG I FOR WHITE LIGHT WITH A 2° FIELD IN THREE RETINAL LOCATIONS

These are at the fovea, and at 5° and 15° above the fovea (The intensities shown must be multiplied by 40 to convert them to the correct intensities, owing to an error in the 1933 paper.)

(Hecht and Verrijp, 1933)

Whiting (1907), Ives (1912), Luckiesh (1914), Allen (1919, 1926), Lythgoe and Tansley (1929), Granit and Harper (1930), and many others. The later experiments by Hecht and Crozier and their associates (Hecht and Verrijp, 1933; Hecht and Smith, 1936; Crozier and Wolf, 1943, 1944; *see also* Landis (1954a) for numerous references to the work of Crozier, Wolf and Zerrahn-Wolf) indicate, however, that the exact relationship is sigmoid in form and that when large central areas are used, or regions in the parafovea, a break in continuity occurs, similar to that observed for other visual functions in accordance with the Duplicity Theory (Hecht, 1935, 1937).

Very complete data over a range of intensities sufficient to cover the entire functional range of the human eye have been obtained by Hecht and his collaborators and their curves provide a convenient basis for discussion. A very full description of their apparatus and the rationale underlying its design is given by Hecht, Shlaer and Verrijp (1933). It was designed to present to the subject a small field of light periodically interrupted and surrounded by a larger field continuously illuminated but otherwise identical with the flickering field. In the early experiments a 10° surround was used but this was later replaced by a 35° surround. Means were provided for controlling and recording the retinal position of the field, its

intensity, spectral composition and the frequency of interruption of its illumination. All measurements were made using an artificial pupil, 1.8 mm in diameter.

Fig. 4.20 shows Hecht and Verrijp's (1933) measurements made with a 2° field in three retinal locations, at the fovea and at 5° and 15° above the fovea. For the fovea, the relation is not rectilinear as was earlier supposed but sigmoid. However, over an intensity range of about two log units the data fall on a straight line with a slope of about the same magnitude as that found by earlier workers. Data for the peripheral fields fall into two parts, suggesting cone function for the high intensity section and rod function for the low intensity section.

Fig. 4.21, taken from Hecht and Smith (1936) shows on a double logarithmic grid the influence of the area of the test-field on the F -log I function, as determined for four centrally-located areas, 0.3°, 2°, 6° and 19° in diameter, using a 35° surround. Whereas the data for the two larger fields (6° and 19°) break into two parts, those for the smaller fields show a single continuous function. The same curve has been drawn through the cone portions of the 19° and 6° data as has been drawn through the 2° and 0.3° data, its equation being—

$$KI = f^2 / (f_{\max} - f)^2 \quad (11)$$

FIG. 4.21. AREA AND THE FLICKER RELATION

The log I axis is the same for all the data. The numbers on the log frequency axis apply to the uppermost data only; the other data have been displaced downward in steps of 0.2 log unit. Their precise position is given on the right. The curves are from Hecht's theoretical equations, as explained in the text.

(Hecht and Smith, 1936)

where I is the intensity, f the logarithm of the C.F.F. and K the dimensional constant which determines the position of the curve on the intensity axis just as f_{\max} determines its position on the frequency axis. Neither K nor f_{\max} affect the shape of the curve on the double log plot.

For the "rod" sections of the 19° and 6° data a somewhat different curve is required, its equation being—

$$KI = f / (f_{\max} - f)^2 \quad (12)$$

The identity of the curves for the rod data and also for the cone data suggests that the differences between the data for different sizes of field are not basic, under the conditions of Hecht and Smith's experiment. "Fundamentally the systems in the rods and cones which determine the relation between critical frequency and intensity remain the same regardless of

Lythgoe and Tansley (1929), Granit (1930), Granit and von Ammon (1931), Creed and Ruch (1932), Rose (1936), Miles (1950), Weekers and Roussel (1948), Riddell (1936), Phillips (1933), Hylkema (1942), Brooke (1951), Lloyd (1942), Monnier and Babel (1952) and Best (1953) show several apparently discrepant findings, some authors finding lower C.F.F.s

FIG. 4.22. INDIVIDUAL CURVES SHOWING THE RELATION BETWEEN CRITICAL FLICKER FREQUENCY AND RETINAL ILLUMINATION FOR A CENTRALLY LOCATED 19' FIELD

Each individual measurement as taken in the course of a run is shown as a dot. For convenience, the separate runs (dated to the right) have been spaced 0.2 log unit apart on the vertical axis; the values on the ordinate scale refer only to the topmost run for each subject. The numbers attached to the rod curves indicate the values of m and n in Hecht's equation used in drawing them. (Hecht and Smith, 1936)

area. Only the dimensional constants are changed by changing the area" (Hecht, Shlaer and Smith, 1935).

To confirm that the two sections of the F -log I data represent "rod" and "cone" function, a further experiment was undertaken with different parts of the spectrum (Hecht and Shlaer, 1936). As expected, for a "red" light of 670 $m\mu$ a single curve was obtained while the remaining wavelengths showed discontinuities corresponding, presumably, to the appearance of rod function. The 670 $m\mu$ data and the "cone" data for all other wavelengths could be fitted by the curve representing equation (11); those for the "rod" portions by the curve for equation (12).

The studies of Hecht and his associates form only a small part of the voluminous psychophysical literature on C.F.F. but there appears to be nothing in this literature which casts serious doubt upon the general form of the F -log I relation which they established for the human eye, although disputes have arisen concerning the effect of retinal location and area of test-field. Studies of regional variation in C.F.F. by

in the fovea than in the periphery, but these discrepancies appear largely due to failure to control pupil size, as Alpern and Spencer (1953) have shown. The better-controlled studies by Brooke (1951) and Lloyd (1942) give results essentially in agreement with those of Hecht and his associates. Lloyd's data on the effects of area also tend to agree closely with those of Hecht.

Other determinants of C.F.F. which cannot be discussed here in detail include the state of light or dark adaptation of the eye and surround illumination (Schaternikoff, 1902; Lythgoe and Tansley, 1929; Geldard, 1932; Fry and Bartley, 1936; Ryan and Bitterman, 1950), duration of exposure of the test-field (Granit and Hammond, 1931; Lythgoe and Tansley, 1929), wave-form (Luckiesh, 1914; Ives, 1922), L.D.R. (Crozier *et al.* (see Landis (1954a) for references); Cobb, 1934; Bartley, 1937; Porter, 1902; Piéron, 1928) and others. For a useful review the reader is referred to Landis (1954b). In general (and there are many discrepancies and complexities) it can

be said that: (1) lower C.F.F.s tend to be obtained under conditions of dark adaptation than under conditions of light adaptation; (2) increasing the surround luminance causes an increase in foveal C.F.F. up to a maximum when surround and test-field luminances are equal, then declines; (3) C.F.F. decreases with an increasing L.D.R. (this is probably the most confused area of the whole subject); (4) larger areas give high C.F.F.s, but do not affect the Ferry-Porter law over a wide range; (5) higher

FIG. 4.23. RELATION BETWEEN FOVEAL CRITICAL FLICKER FREQUENCY AND ILLUMINATION

Data for S.H. recording the 176 separate measurements.
(Hecht and Verrijp, 1933)

C.F.F.s are obtained with increasing length of exposure from 0.1 to 1 second.

Measurements by Hecht and Crozier and their associates indicate that C.F.F. data are highly reproducible when made under carefully specified conditions. Thus marked similarity is found in the shape of the F -log I function obtained from different trained subjects and in the same subject on different occasions. Comparison of the curves for Hecht and Smith obtained on three different occasions is shown in Fig. 4.22. The slopes of the straight line portion of Hecht and Verrijp's (1933) curves are 11.1 and 11.0 respectively, and most of the carefully controlled experiments give values of about 11. Some indication of the scatter that occurs over a long period of time is given by Fig. 4.23 which shows the individual measurements made by Hecht for a foveal test-field over a year and a half. (The curve drawn through the data is the same one as is drawn through the average data in Fig. 4.20.)

Data on variation in larger groups of subjects relate only to a very restricted range of experimental conditions, e.g. to a single size of test-field, luminance level, retinal location, etc., but provided the experimental conditions are well-controlled, it is usually found that the range of variation is relatively small. Keys and Simonson (1952) for instance, found in a group of one hundred and three normal males (aged

52 ± 2.9 years) that the mean C.F.F. was 42.8 and the standard deviation 2.2. Retest data obtained by McNemar (1951) after one week correlated 0.97 with the original measures. Simonson and Brozek (1952) report a correlation of 0.98 over the same period of time.

Possible sources of individual variation include both physical and biological factors and their relative contribution to the total variance will vary depending upon experimental conditions. Thus, in the carefully controlled experiments of Hecht and Crozier purely physical sources of variation are reduced to a minimum but may be considerable in many of the studies with clinical groups. Possible physiological sources of variation include changes in pupil size and the transmission factor of the lens and ocular media. Variation in these components accounts at least in part for age changes in C.F.F. observed by Simonson, Enzer and Blankstein (1941a), Brozek and Keys (1945), Misiak (1947), Weekers and Roussel (1948) and Berg (1949). Within the sensory system itself variations may occur due to the effect of beverages such as coffee, alterations in breathing pattern, smoking, etc.

That C.F.F. is, as some authors suggest, related to relatively permanent characteristics of the individual which operate as personality traits in a variety of different functions remains to be demonstrated. Results of several studies have indicated a tendency for "perseverators" to have lower C.F.F.s than "non-perseverators" (Wiersma, 1906; Lankes, 1915; Biesheuvel, 1938) and "extraverts" to have lower C.F.F.s than "introverts" (Washburn *et al.*, 1930; Madlung, 1935; Simonson and Brozek, 1952) but the operational definitions of these traits differ from one study to another and, with the possible exception of Simonson and Brozek's study, full details of which have not been published, experimental conditions are inadequately specified and controlled. An interesting study which bears on the interpretation of individual variation in terms of personality variables is that of McNemar (1951) who has shown the marked extent to which correlations can be reduced by relatively slight variations in stimulus conditions.

PHYSIOLOGICAL DATA AND THEORIES

(a) Photochemical Theories

Theories of C.F.F. are of two main types, those that put chief emphasis on peripheral (retinal) determinants and those which emphasize more central factors. Further subdivisions may be made in the case of retinal theories into photochemical and neural. Apart from the importance to visual theory of determining the critical structures and mechanism of C.F.F., elucidation of the part played by the retina, cortex and other components of the visual system is

important also for the interpretation of changes in C.F.F. occurring in abnormal conditions.

Although theories of "intermittent vision" were proposed by Fick (1863), S. Exner (1870), K. Exner (1870), Ives (1922) and others, it was not until the publication of Hecht and Verrijp's (1933) paper that there was a really comprehensive theory available to describe the quantitative data of flicker. In presenting their theory Hecht and Verrijp stated quite explicitly that it was to be regarded only as a first approximation.

"The retina is a complicated structure, and not enough is known about it to furnish the material for an adequate formulation of so complex a phenomenon as flicker. However, no matter what else occurs in the retina, the very first step in vision must involve a photochemical change having certain fairly well defined characteristics. Since the products of this photochemical change serve only to *start* the complicated train of events which finally yield a series of impulses in the optic nerve, it cannot be expected that the behaviour of the photochemical system alone will yield a complete description of the receptor process. Nevertheless because quantitative ideas are available in photochemistry it is necessary to discover how far this very first photochemical transformation can go in characterizing the receptor process as a whole" (Hecht and Verrijp, 1933, p. 273). Later in the same article Hecht and Verrijp emphasize that, "The photochemical derivation is for a homogeneous system, and applies to a given cell or to a number of cells of identical properties" (*ibid.*, p. 278).

The derivation presented here is a later and simpler form of that given in the 1933 paper. In presenting it, reference will be made to equations discussed earlier in the section dealing with intensity discrimination.

Whereas brightness discrimination and visual acuity could be considered in terms of the stationary state of the primary light and dark reactions, in deriving equations for flicker Hecht had to take into account the secondary dark reaction which follows them. The velocity of the combined primary reactions as they occur under the influence of light is given by—

$$(dx/dt)_l = k_1 I(a - x)^m - k_2 x^n \quad (13)$$

from equations (3) and (4). The rate at which the sensitive material is formed when, in the absence of light, the primary dark reaction proceeds alone, is given by equation (4).

When the illumination is intermittent the two reactions alternate rapidly and form a steady state. In the case where the L.D.R. is 1:1 the light and dark velocities will be equal. Putting equation (13) equal to equation (4) and solving gives—

$$KI/2 = x^n/(a - x)^m \quad (14)$$

Except for the number 2 in the denominator which depends on the equality of light and dark periods this equation is identical with the stationary state equation. For other values of the L.D.R., 2 would be replaced by another number, this being the reciprocal of the fraction which the light duration is of the total light and dark cycle. Equation (14) is the basis of Talbot's law.

Hecht's treatment of C.F.F. is as follows. The effect of light on the sensitive material is carried forward by

FIG. 4.24 THE STATIONARY STATE EQUATION PLOTTED WHEN m AND n ARE EACH 1 AND 2

Because of the double log plot the shape of the curves remains constant regardless of the values of K and a which merely locate the position of the curves on the axes.

(Hecht and Smith, 1936)

the secondary dark reaction which the photoproducts undergo. The concentration of these photoproducts is x (equation (14)), therefore the rate of the secondary dark reaction is—

$$(\Delta x/\Delta t)_{\text{secondary}} = k_3 x \quad (15)$$

where k_3 is a velocity constant. C.F.F. represents the situation in which $\Delta x = c'$, that is, the change Δx in concentration in the dark time Δt is just too small to cause the physiological change that underlies the change in the visual brightness response. If the critical flicker frequency is f cycles of light and dark flashes per second, $f = 1/2\Delta t$. Substituting these values of Δx and Δt in equation (15) gives—

$$f = cx \quad (16)$$

where $c = k_3/2c'$. Thus, C.F.F. is directly proportional to the concentration of photoproducts in the stationary state, as given by equation (14).

Fig. 4.24 shows a plot of the steady state equation when m and n are each 1 and 2; as in the case of the curves for brightness discrimination and visual acuity, their shape remains constant regardless of the values of K and a . The values of n determine the slope of the

steep limb of the curves while m determines the curvature of the bend joining the steep limb with the horizontal one.

Reference to the experimental data on the F -log I function shows that the slope of the rod curve is always twice that of the cone curve and this determines the value of n in the two cases. The best fit to the cone data is always obtained when m and n are both equal to 2, as in the case of brightness discrimination and acuity. The rods tend to be more variable in respect of the value of m .

Although Hecht's equation accounts satisfactorily for a wide variety of flicker data obtained from man and other animals, it fails to account for the data of *Pseudemys*, *Sphaerodactylus* and *Asellus* (Crozier and Wolf, 1939; Crozier, Wolf and Zerrahn-Wolf, 1939a, b), and the observed shift in the F -log I curve following change in L.D.R. (Bartley, 1937; Crozier, Wolf and Zerrahn-Wolf, 1938a, b; Crozier and Wolf, 1940, 1941b, c) or temperature (Crozier, Wolf and Zerrahn-Wolf, 1937a) is opposite to that predicted from theory. To overcome these difficulties Jahn (1946a) has proposed a modification of Hecht's equation, based on more recent information about the events of the photochemical cycle. Jahn's equation has the same general form¹ as Hecht's so that it will fit all the experimental data that could be fitted by the old equation but the parameters of the two equations have a different significance. The new equation also accounts for the data on L.D.R., temperature, etc. An important difference between Jahn's theory and the earlier scheme of Hecht is that Jahn assumes that the value of the maximal C.F.F. is determined not by the photochemical cycle but by some other process which is unaffected by temperature.

(b) Neural Theories and Electrophysiological Data

Theories which assume that the shape of F -log I curves is determined by properties of the central nervous system rather than by the photoreceptors have been proposed by Crozier and his associates (see Landis (1954a) for references) and by Householder and Landahl (1945). From these theories, which rest on certain assumptions about the statistical and mathematical properties of central nervous activity (see section on Brightness Discrimination and Visual

Acuity), equations¹ can be derived which provide a reasonably good fit for some of the psychophysical data. To the extent that they predict S-R data the theories may be of value from a purely behaviourist point of view but from their very nature they cannot provide any detailed information on the relative contribution of specific structures to the phenomena of sensory flicker and fusion.

Information of this kind can only come from direct physiological analyses. Although they do not yet provide a basis for quantitative treatment of flicker data, electrophysiological experiments have already shown that retinal structures play a major part in the determination of sensory fusion. In the first place, the human electroretinogram, evoked by intermittent stimuli, shows a fusion of electrical responses at a frequency close to that of the C.F.F. determined by sensory methods (Dodt, 1951a) provided sufficiently intense stimuli are used. The upper limit is about 60 c/s in the light-adapted eye, while the fusion frequency recorded from the ERG of a dark-adapted eye is low, upper limit about twenty-five flashes per second, as found also in psychophysical research (Bernhard, 1940; Monnier, 1949). Further parallels between electrophysiological and psychophysical records appear when the effects of luminance², size of test-field, and state of adaptation are considered (Creed and Granit, 1933; Granit and Riddell, 1934; Granit and Therman, 1935). These results suggest that fusion is determined to a large extent in the retina. Moreover, as it now seems likely that the ERG is an almost pure receptor potential (Ottoson and Svaetichin, 1952, 1953; Noell, 1953; Brindley, 1956) the experiments on the human ERG would suggest that fusion may be determined in the receptors themselves.

Electrophysiological research has also contributed to our understanding of the mechanisms involved in flicker and fusion, in particular the part played by inhibition. According to Granit's component analysis of the ERG, PIII the negative component identified for various reasons with inhibition, plays an important part in determining the eye's responses to fast rates of intermittence, marked PIII activity being associated with a high C.F.F. and little or no PIII with a low C.F.F. (Granit, 1947). Granit's ERG analysis of flicker has been supplemented by more recent research on single retinal elements by Enroth (1952) in which she confirmed the earlier analysis and demonstrated in greater detail how flicker responses depend upon an interaction between excitation and inhibition.

¹ Jahn's equation for C.F.F. is—

$$F = \frac{k_4 P}{C'} \left[k_1 I(a - x) \right]^q (F_{\max} - F)^r$$

where F is the critical flicker frequency, x is the amount of P or A , $(a - x)$ is the amount of S , I is intensity, P is the fraction of the flicker cycle during which the light is on, k_4 is the velocity constant of the LT reaction (see page 139) q refers to the mechanism whereby the photoproduct E is utilized by the sense cells and r denotes a mathematical function of F (Jahn, 1946a).

¹ To describe some of his early measurements on the C.F.F./log intensity function Crozier used a logistic which was formally identical with Hecht's stationary state equation but he later found that a normal probability integral gave a somewhat better fit to both his animal and human data.

² See, especially, the results of recent research on the human retina reviewed by Granger and Ikeda (1959b).

Having analysed the fusion frequency of intermittent stimuli for single retinal elements she went on to study its relation to impulse frequency in a large assemblage of elements. The important generalization from this later work (Enroth, 1953) was that fusion frequency is directly proportional to impulse frequency. As fusion frequency is also a measure of brightness (the Ferry-Porter law), brightness now appears as a simple function of impulse frequency (cf. Adrian, 1928; Granit, 1955).

One further finding which may be mentioned is that of Svaetichin (1956). He observed a striking parallelism between the amplitude of the fish cone response for different light intensities (Fig. 4.25) and the "cone" portion of the sunfish's F -log I curve, as determined by Wolf and Zerrahn-Wolf (1936) using the optomotor response technique (Fig. 4.26). It will be observed that the two curves are very similar between 3 and 0 on the log mL scale. The significance of Svaetichin's finding for human vision comes from the fact that the F -log I curve for the sunfish is similar to the human curve (Fig. 4.26).

In the light of this recent electrophysiological research on the retina it is surely no longer "puzzling why the view of the exclusive or at least primary role of the retina has found such emphatic proponents" (Simonson and Brozek, 1952), although it was perhaps

more puzzling at the time when Simonson and Brozek made these comments. However, even though there is evidence that the primary mechanism of fusion is peripheral it is doubtful if anyone would maintain

FIG. 4.25. THE RELATION BETWEEN AMPLITUDE OF THE FISH "L" CONE RESPONSE AND LOG INTENSITY OF THE LIGHT STIMULUS

"L" refers to one of three fundamentally different types of spectral response curve obtained from *Teleost* fish cones; it was labelled "L" "since it seems to correspond well to the luminosity mechanism."

(Svaetichin, 1956)

FIG. 4.26. THE RELATION BETWEEN CRITICAL FLICKER FREQUENCY AND LOG INTENSITY OF THE LIGHT STIMULUS

Left: curve obtained from the sunfish (*Lepomis*) using the optomotor response method.

(Wolf and Zerrahn-Wolf, 1936)

Right: curve for man obtained using the same method.

(Crozler, Wolf and Zerrahn-Wolf, 1937b; after Bartley, 1951)

that all the psychophysical data of flicker fusion are peripheral in origin. Having claimed that "the main characteristics of flicker and fusion are determined by the time constants of the photoreceptor responses," Svaetichin goes on to say that: "It cannot be excluded . . . that certain subtle phenomena noticed in the analysis of the perception of flicker and fusion may be caused by an activity at different levels of the visual pathways" (Svaetichin, 1956, p. 53). Svaetichin's comments apply particularly to phenomena noted by Bartley, such as brightness enhancement (Bartley, 1939, 1941). Evidence for central facilitation or inhibition comes from comparison of the results of binocular and monocular presentation (Ireland, 1950; Crozier and Wolf, 1941*a*) under conditions of in-phase and out-of-phase stimulation, and from various studies of cerebral action potentials (*see* Simonson and Brozek, 1952, for review).

ABNORMAL CONDITIONS

In contrast to the extensive data on brightness discrimination relatively few data are available dealing with the effects of physiological stresses on the F -log I function. Seitz (1940) investigated the effect of anoxia on the F -log I curve over an intensity range of about 4 log units for a centrally fixated 6' test-field and found that oxygen deprivation equivalent to that at 17,500 ft and 20,000 ft reduced C.F.F. for both cone and rod portions of the curve. Unfortunately his data do not cover a sufficiently wide range of intensities to determine whether the curve was shifted along the intensity axis or along both axes. Lowered foveal C.F.F.s were also found by Birren, Fisher, Vollmer and King (1946) at simulated altitudes of 10,000, 14,000, 15,000 and 18,000 ft. (The decrement in C.F.F. was uncorrelated with decrements on a visual field and body-sway test.)

Long latent periods in the C.F.F. response to anoxia were noted in both investigations. Up to thirty minutes' exposure was often necessary before the effect of 20,000 ft altitude could be detected in Seitz's investigation. Changes were still progressing after ninety minutes of exposure and recovery in atmospheric air took over thirty minutes. As Simonson and Brozek (1952) have remarked, these changes are surprising in view of the speed of changes in the blood gases. They suggest that the slowly progressive decrease of C.F.F. under these conditions is due to "a cumulative anoxic effect, possibly involving accumulation of metabolites." Breathing of pure oxygen can cause return to normal C.F.F. values within ten minutes.

Gellhorn and Hailman (1944) claim that parallel changes occur in C.F.F. and in the EEG during anoxia but unfortunately they do not provide sufficient information about the conditions of their C.F.F.

apparatus to enable the study to be properly evaluated. The results of various studies of anoxia have been conveniently summarized in Simonson and Brozek (1952, p. 11).

Rubinstein and Therman (1935) observed a significant increase in C.F.F. following two minutes of voluntary hyperventilation. The mean increase for a central area of 1° and a peripheral area of 4° was 3.5 flashes per second and for a 4° centrally-fixated area, 5.3 flashes per second. More recently Alpern and Hendley (1952) have attempted to determine whether the effect is due to changes in the hydrogen ion concentration of the blood or to a direct effect of carbon dioxide. Measurements were made using a test-field of 2.3° angular diameter, surrounded by an annular background 6° in diameter. The L.D.R. was 1:1 and observations were made through a 2-mm artificial pupil. The luminance of the surround was kept equal to the Talbot luminance of the flickering test-field. Metabolic acidosis was produced by the oral administration of ammonium chloride (4–8 mM/kg taken over a period of 24 to 36 hours) and metabolic alkalosis was produced by the oral administration of sodium bicarbonate (8–12 mM/kg taken over a period of 1 to 6 hours). Respiratory acidosis was produced by asking the subject to breathe a mixture of 7 per cent carbon dioxide and 93 per cent oxygen and respiratory alkalosis was produced by voluntary hyperventilation. Blood samples were taken using the method of Dautreband (1926) and the blood pH, HCO_3 and pCO_2 were determined according to Davenport (1950).

Results showed that although slight changes in C.F.F. occurred with metabolic acid-base changes (acidosis produced lowered C.F.F. and alkalosis raised C.F.F.) the effects were not significant. On the other hand, respiratory acidosis was associated with a marked decrease (4 c/s) at the two luminance levels studied and respiratory alkalosis was associated with a rise in C.F.F. between 3 to 5 c/s; both effects were statistically significant ($p < 0.001$). Fig. 4.27 shows, in a F -log I plot, the results obtained from twelve normal young adults.¹ It is unfortunate that these curves are based on so few experimental points although those plotted appear to have been reliably determined. The general form of the curve suggested by Alpern and Hendley's data is essentially similar to the F -log I curve of Hecht and Verrijp (1933) for a foveal test-field. (A depression in C.F.F. beyond the maximum was observed, when Hecht and Verrijp used a surround of 10°, which is of the same order as the size of the surround used by Alpern and Hendley.) The slope of the straight line portion of the curve (Ferry-Porter law) is 10, which also agrees fairly well

¹ The authors do not give a detailed account of their results but state that these will be published in full elsewhere.

with previous measurements. The data suggest that respiratory acidosis and alkalosis cause a shift of the entire curve along the frequency axis, downward in the former case and upward in the latter. From their results the authors conclude that the changes in C.F.F. are not due to changes in the blood pH *per se* but are indices of variation of the blood $p\text{CO}_2$.

Recent unpublished experiments by Granger and Ikeda confirm and extend Alpern and Hendley's findings concerning the effects of hyperventilation on the C.F.F./intensity relation and suggest that they are associated with the problems of areal variation in the C.F.F. and spatial summation in the visual system. Working with centrally-fixated fields ranging in size from a few minutes of arc to about 2° they found a pronounced increase of 2–3 c/s with the larger fields but none at all with the very small ones. Their suggestion that hyperventilation increases spatial integration is based on curves showing the relation between area and intensity for a fixed value of the C.F.F.

Studies of the effects of drugs are fairly consistent in showing that C.N.S. stimulants such as amphetamine (Simonson, Enzer and Blankstein, 1941*b*; Roback, Krasno and Ivy, 1952), caffeine (Schmidtke, 1951; Muecher and Wendt, 1951) and Dexedrine (Roback, Krasno and Ivy, 1952) raise C.F.F. while depressants such as barbiturates (Simonson and Brozek, 1952; Roback, Krasno and Ivy, 1952; Idström, 1954) and alcohol (Enzer, Simonson and Ballard, 1944; Goldberg, 1943) lower C.F.F. Of the various drugs that have been used (for a review see Simonson and Brozek, 1952) alcohol is of particular interest because Goldberg has established that a quantitative relationship exists between C.F.F. changes and the blood-alcohol level.

Following its early application in ophthalmology (Braunstein, 1903) C.F.F. measurement has more recently been applied to problems in other branches of medicine. Lowered C.F.F.s have been reported in cardiovascular disorders (Enzer, Simonson and Blankstein, 1942; Krasno and Ivy, 1950), metabolic diseases such as hypothyroidism (Enzer, Simonson and

Blankstein, 1941), multiple sclerosis (Parsons and Miller, 1957) and lesions of the visual pathways (Phillips, 1933; Battersby, 1951; Battersby *et al.*, 1951). Claims that lesions of the frontal lobe lead to a depression of C.F.F. (Halstead, 1947) have not been substantiated (Battersby, 1951; Battersby, Bender and Teuber, 1951) although they may, under certain conditions, lead to transient changes (Young, 1949; Nolan, Lewis, Landis and King, 1956). Berg (1949)

FIG. 4.27. THE EFFECT OF RESPIRATORY ACIDOSIS AND ALKALOSIS ON THE RELATION BETWEEN CRITICAL FLICKER FREQUENCY AND ILLUMINATION (Alpern and Hendley, 1952)

and Akerlund (1953) found a lowering of C.F.F. under Evipan in cases of diffuse brain injury, but Blomberg (1955) has failed to confirm their findings. A detailed account of Berg's research is given in Zubin *et al.* (1957).

Possible psychiatric applications of C.F.F. measurement are suggested by the results of several studies in which "anxiety," variously defined, was associated with a lowered C.F.F. (Krugman, 1947; Goldstone, 1953, 1955; Bühler, 1954; Kubzansky, 1954), but Ricciuti (1948) found no differences between groups of neurotic, psychotic and normal subjects. More detailed accounts of the confused literature on psychiatric patients will be found elsewhere (Zubin *et al.*, 1957; Granger and Ikeda, 1959*b*).

III. ADAPTATION

PSYCHOPHYSICAL DATA

The term "dark adaptation" refers to the improvement in visual sensitivity which occurs during a stay in the dark after exposure to light. First described by Aubert (1865) it has since been investigated frequently in man and other animals (see Adams, 1929; Müller, 1932 and Hecht, 1934 for reviews of the early literature). Only a small fragment of the enormous literature, sufficient for an understanding of theories

of adaptation and the effect of abnormal conditions will be discussed here.

The earliest measurements were made by Piper (1903) using large test-fields, peripheral observation and white light. The data showed a continuous decrease in threshold extending for about thirty minutes and covering an intensity range of about 5,000:1. The increase in sensitivity was attributed to the rods owing to the peripheral nature of the measurements.

That adaptation can occur also in the cones was suggested by the early experiments of Nagel and Schaefer (1904), Inouye and Oinuma (1911) and Dittler and Koike (1912) and clearly demonstrated by Hecht (1921). Hecht found that following five minutes' exposure to a luminance of 90 mL the change in threshold of the fovea was of the order of 6 or 7:1 and dark adaptation was almost complete in four to

FIG. 4.28. DARK ADAPTATION OF THE EYE AS A WHOLE
Piper's (1903) data, re-plotted by Hecht
(Hecht, 1937)

six minutes. His results have since been confirmed by Kohlrausch (1931), Crawford (1946), Graham (1930), Johannsen (1934) and others.

As both rods and cones show adaptation, data from the human eye as a whole display both phenomena as Kohlrausch (1922) first demonstrated in a retinal area containing both rods and cones. He found that the dark adaptation curve for this area showed two distinct segments apparently related to cone and rod function. A curve of this type is shown in Fig. 4.28. Such a curve has often appeared in textbooks as a "typical" dark adaptation curve but whether or not one of this type is obtained depends upon a number of conditions. Kohlrausch's (1922) data obtained for a 1° field situated 5° above the fovea show, for instance, that the colour of the test-light is important in determining the characteristics of the curve (Fig. 4.29). Of great importance also is the intensity and duration of the preceding light adaptation. Thus, even in the case of threshold data obtained with a "blue" test-light which show hardly any cone adaptation in Kohlrausch's study (lowest curve of Fig. 4.29) cone adaptation may become strikingly apparent provided the previous light adaptation has been sufficiently intense, as shown by Hecht and Haig (1936).

The effect of varying the intensity of light adaptation is brought out particularly well in Fig. 4.30, taken from Hecht, Haig and Chase (1937), which shows a family of dark adaptation curves following two-minute

exposures to various intensities of retinal illumination. (The filled-in circles indicate that the test-field appeared violet, while the open circles indicate that it appeared colourless.¹) According to these results, the degree of adaptation which is reached in a given time varies inversely with the level of pre-adaptation; the cone-rod transition time is progressively delayed as the light adaptation is increased although the intensity of the test-field at which it appears is approximately constant.

According to Haig (1941), the effect of varying the duration of previous light adaptation is similar to that of varying the intensity. Increasing the degree of light adaptation, whether by varying intensity or duration, caused a reduction in the rate of rod adaptation in his experiments. The change of rate had two components, a decrease in slope and a displacement to the right along the time axis, the first effect being more marked after lower degrees of light adaptation, and the second after the higher ones. Haig suggested that his results were an expression of the Bunsen-Roscoe law.

FIG. 4.29. THE DARK ADAPTATION OF AN AREA 1° IN DIAMETER, SITUATED 5° ABOVE THE FOVEA
(Kohlrausch's 1922, 1931 data, after Hecht, 1937)

Haig's results are at variance with earlier findings of Wald and Clark (1937) who found that duration and intensity were not interchangeable variables as far as subsequent dark adaptation is concerned. The problem has recently been investigated by Mote and Riopelle (1953) under a very wide range of intensity

¹ Use of a "violet" test-field is a valuable means for helping to make distinct the cone-rod transition point and is part of the standard procedure adopted in routine tests with the Hecht-Schlaer adaptometer.

and duration. They found that the reciprocity relationship holds in the case of the parafoveal dark-adaptation curve over a range of intensity and duration of the order of 1,000:1 but breaks down beyond that range. Limitations to the range of application of the reciprocity law have been observed also in studies of foveal adaptation (Crawford, 1946; Mote and Riopelle, 1951; *see also* Johannsen, McBride and

et al., 1953). Increasing the area or duration of the test-stimulus tends, within certain limits (but *see* Rushton, 1952) to shift both the cone and rod portions of the curve downward along the intensity axis, while stimuli making demands upon visual resolution or "form" perception tend to cause an upward displacement (Brown, 1954). In the latter connexion it should be noted that in certain cases the increase in luminance

FIG. 4.30. THE COURSE OF DARK ADAPTATION AS MEASURED WITH "VIOLET" LIGHT FOLLOWING DIFFERENT DEGREES OF LIGHT ADAPTATION

(Hecht, Haig and Chase, 1937)

Wulfeck, 1956). All these studies on the effects of varying degrees of light adaptation are of great importance in connexion with theories of dark adaptation (*see* later discussion).

Other studies with less direct bearing on the problems of this chapter concern the effects of variations in size of the adapting field (Honda, 1952), spectral distribution of the adapting-light (Hecht and Hsia, 1945; Smith, Morris and Dimmick, 1954), the influence of intermittent pre-adaptation (Mote, Riopelle and Meyer, 1950) and distribution of light in the adapting field (Baker, Debons and Morris, 1956).

In addition to the effects of wavelength already considered, other characteristics of the test-field that affect dark adaptation curves are area (Wald, 1938), duration (Wolf and Zigler, 1951) and stimulus pattern (i.e. whether a patch of light or more complex form is used for threshold measurement (Brown, J. L.

thresholds is due simply to a reduction in area illuminated (Miles, 1953; Granger, 1957). Taking quantum considerations into account (Pirenne, Marriott and O'Doherty, 1957) the distinction between "light sensitivity" and "form perception" at low intensities is not so sharp as has sometimes been supposed (cf. Craik and Vernon, 1942 and *see* page 111).

Provided adequate care is taken with the measuring technique, foveal and parafoveal dark adaptation curves for different individuals and for the same individuals at different times tend to be very similar in shape. The curves shown in Fig. 4.31 are taken from Hecht, Haig and Chase (1937) and those in Fig. 4.32 from Hecht (1921). Experiments made by other workers (e.g. Pirenne *et al.*, 1957; Granger, 1957c) confirm the high degree of reproducibility of the course of dark adaptation and the relatively small amount of individual variation when Hecht's "fixation-and-flash" technique is used (Hecht and Schlaer,

FIG. 4.31. [DARK ADAPTATION FOLLOWING THREE DIFFERENT INTENSITIES OF LIGHT ADAPTATION

Coloured "cone" thresholds are plotted separately from colourless "rod" thresholds. The abscissae are the same for all the data; the ordinate scale, however, applies only to the topmost data, the other two sets have been displaced 0.5 and 1.0 log unit downward, respectively

(Hecht, Halg and Chase, 1937)

FIG. 4.32. INDIVIDUAL FOVEAL DARK ADAPTATION CURVES FOR FIVE SUBJECTS

Each point is the average of two readings, one for the left, and one for the right eye.

(Hecht, 1921)

1938). Less controlled methods of threshold determination, particularly the use of a fixation point with continuous viewing (Craig and Vernon, 1941) can lead to large individual variation due to the influence of "local adaptation" effects (Pirenne, Marriott and O'Doherty, 1957)¹ and regional variations in retinal sensitivity. Fig. 4.33, taken from Pirenne, Marriott and O'Doherty (1957) shows a fairly typical variation in cone-rod transition time between six and eight

0.80 log unit, and the variation in cone-rod transition time six to nine minutes. It is interesting to note that the range of variation in (mean) threshold values for the population of subjects in Hecht and Mandelbaum's (1939) study is of the same magnitude as the range of "uncertain seeing" in a single subject on a given occasion (Pirenne, 1956).

A tendency for final cone and rod threshold to vary in the same direction, as determined by correlating

FIG. 4.33. INDIVIDUAL DARK ADAPTATION CURVES FOR EIGHT SUBJECTS, MEASURED BY THE HECHT-SHLAER (1938) METHOD
(Pirenne, Marriott and O'Doherty, 1957)

minutes and a range of variation of 0.5 log unit at the final threshold.

Data from relatively unsophisticated subjects in large-scale clinical studies scatter more widely but the general similarity among individuals is still apparent. Fig. 4.34 is taken from Hecht and Mandelbaum's (1939) investigation of one hundred and ten normal subjects. Measurements were single readings and represented first performances. At the final rod threshold the range of threshold values is approximately 1 log unit, the range of cone thresholds about

individual threshold values, has been observed in several investigations. Hecht and Mandelbaum found a product-moment correlation of 0.44, Sheard (1944) found a correlation of 0.63 and Birren and Shock (1950) one of 0.64, using similar techniques. Hammond and Lee (1941) reported a correlation of 0.39 between thresholds at ten minutes and forty minutes from the beginning of dark adaptation. The same authors found that the final rod threshold was independent of the rate of adaptation ($r = -0.06$) while Birren and Shock (1950) found that both the final cone and rod thresholds were independent of the rate of cone and rod adaptation ($r = 0.05$ and 0.18 , respectively).

A maximum day-to-day variation of about 0.3 log unit in final threshold has been found by Hecht and his associates (Hecht and Mandelbaum, 1939), although smaller variation than this is commonly

¹ Hecht, Haig and Chase had the following to say about variation in dark adaptation data: "In our experience of over ten years, we have found that most of the variations in the data arise from failure to specify conditions of measurement. The major differences may be eliminated by fixing the intensity and duration of light adaptation, and the position, area and colour of the light used for measuring dark adaptation (Hecht, Haig and Chase, 1937, p. 841).

reported among trained observers under well-controlled conditions over considerable periods of time (Sheard, 1944). Sometimes, however, sudden changes of threshold may occur following a severe cold or "for no apparent reason" (Hecht and Mandelbaum, 1939). Variations of the order of 0.3 log unit have also been observed in tests carried out on the same

FIG. 4.34. THE COURSE OF DARK ADAPTATION IN ONE HUNDRED AND TEN SUBJECTS

The points represent the single measurements made with two subjects yielding the highest and lowest values of the final threshold. The dotted area contains 80 per cent of the population. The "cone" adaptation is marked with filled circles, the "rod" with open circles.

(Hecht and Mandelbaum, 1939)

person at different times during the day (Pirenne, Marriott and O'Doherty, 1957).

Sources of normal variation of threshold values in well-controlled studies must include, in addition to changes due to quantum fluctuations in the stimulus, changes in the properties of the pre-retinal eye media, receptors, retinal synapses and visual pathways. Under other conditions, (e.g. many clinical investigations) to these factors must be added variations in physical conditions of the experiment, pupil size, eye movements and other non-sensory factors. The effect of age in raising rod and cone thresholds, though not apparently the *rate* of adaptation (Birren and Shock, 1950) is probably mediated by increasing opacity of the ocular media and reduced pupil size (this has not been controlled in some of the experiments) as well as by changes in the nervous system.

Physiological mechanisms responsible for producing day-to-day variation in the state of the visual system remain to be analysed but already some of the variables are known. McFarland and Forbes (1941) have, for instance, shown that variation in blood-sugar concentration is important (cf. experiments on insulin hypoglycaemia, page 142); comparing dark adaptation curves obtained before and after breakfast, when

the blood sugar varies from about 80 mg per cent to 100–120 mg per cent, they found a mean difference of 0.3 log unit; a decrease in threshold following breakfast was observed in nine out of ten subjects (see Fig. 4.35). The authors consider that "this degree of variation, the amount attributed by Hecht and Mandelbaum (1939) to intra-individual variation during the day or from day to day, may be accounted for by the variations in the blood sugar in relation to meals" (McFarland and Forbes, 1941). This is perhaps somewhat optimistic but further experiments along the same lines (e.g. varying the amount and type of food ingested (Sheard, 1944), breathing pattern, etc.), if supplemented by animal experiments, should eventually lead to an understanding of the physiological mechanisms involved.

PHYSIOLOGICAL FACTS AND THEORIES

(a) Photochemical Theories

Theories of visual adaptation are of two types, those which claim that adaptation is photochemical in origin and those which maintain that changes occur also in neural mechanisms. The basic formulation of photochemical theory is due to Hecht (1919, 1920, 1921) and has already been considered both in general terms and in its application to intensity discrimination. Applied to visual adaptation, the photochemical theory states that during light adaptation rhodopsin

FIG. 4.35. THE MEAN DARK ADAPTATION CURVES FOR TEN SUBJECTS IN THE BASAL AND NON-BASAL STATE

(McFarland and Forbes, 1941)

and other visual pigments are bleached and products formed which are insensitive to light. The effect of bleaching is to lower the concentration of sensitive material in the retina and, hence, the sensitivity of the visual mechanism to light. Recovery of sensitivity during darkness is due to the resynthesis of the sensitive material from its photoproducts. On this

theory the absolute threshold is conceived as some simple function of the concentration of sensitive material in the photoreceptors. Following Hecht, the theory may be stated qualitatively as follows—

Under stimulus of light a photochemical substance, S , is split into two photoproducts, P and A . Freshly formed $P + A$, denoted by $\parallel P + A \parallel$, catalyses a further reaction ($L \rightarrow T$) which is non-light sensitive and results in the formation of an active substance (T) from the inactive substance (L). T initiates the nerve impulse. P and A combine in the dark to reform the photosensitive material, S , and this reaction, plus the photochemical breakdown, is the basis of threshold changes that occur during light and dark adaptation. On this theory changes do not occur in the nervous system; the latter's role is merely that of a conducting mechanism which transmits the effects of photochemical changes to the brain. Following the general formulation of photochemical theory given on page 118, we may consider a situation where the degree of light adaptation is sufficient to bleach almost the whole of the photosensitive substance, S . Under these conditions the initial concentration a will equal x . After a period of time t in the dark when some regeneration has occurred, the concentration of S will be $(a - x)$, x being obtained by integrating equation (4) on page 119. It can then be shown that when the order n of the reaction is 1, $(a - x) = a(1 - e^{-k_2 t})$, and when $n = 2$, $(a - x) = ak_2 t / (1 + ak_2 t)$.

Although Hecht had some success in accounting for the dark adaptation data of various invertebrates such as *Mya*, on which his analysis was largely based, difficulties have arisen in attempting to apply the theory to direct measurements of the regeneration of rhodopsin¹ (Tansley, 1931; Zewi, 1940; Peskin, 1942) and to human dark adaptation data. Even when his initial assumption of direct proportionality between concentration and $1/\log$ threshold intensity was discarded in favour of the assumption that concentration is proportional to $1/\text{threshold}$ (Wald, 1944) the experimental data could still not be satisfactorily fitted. Discrepancies arose particularly from experiments in which the degree of light adaptation was varied over a wide range. Whereas, according to Hecht's original theory, recovery curves following various degrees of light adaptation should retrace one another's paths and merely be displaced along the time axis, the actual data reveal marked differences in shape (see Thomson, 1950).

A modification of Hecht's theory has been proposed

by Moon and Spencer (1945), in which they introduce various complications into the equations. Exponentials are introduced into equation (3) and several terms in equation (4), including an hysteresis integral which makes the rate of regeneration at any given time depend on the entire previous history of the process as well as its present state. Accepting Hecht's assumption that the threshold is reached at a given rate of decomposition, Moon and Spencer develop an elaborate mathematical structure from which they are able to derive expressions which agree with data not fitted by Hecht's equations (e.g. Haig's 1941 results).

A serious objection to both this and the earlier theory is that they rest on too simple a conception of the recovery mechanism: only the reversibility of the primary reaction is considered whereas it is now known to be more complicated than this. A modification of photochemical theory based on more recent information concerning the photochemical cycle has been proposed by Jahn (1946c), who assumes two reactions, one of which is bimolecular, starting from retinene and the other auto-catalytic, starting from vitamin A. In Jahn's view rhodopsin acts as a catalyst for the second of these reactions the speed of which is thus proportional to the product of the concentration of vitamin A and rhodopsin. From this modified theory Jahn can derive equations which provide a fairly satisfactory description of the family of recovery curves after different amounts of light adaptation (cf. Haig, 1941).

(b) Neural Mechanisms in Adaptation

Numerous objections have been raised against a purely photochemical explanation of visual adaptation by Lythgoe (1940), Granit, Holmberg and Zewi (1938), Elsberg and Spatnitz (1938), Granit, Munsterhjelm and Zewi (1939), Schouten and Ornstein (1939), Baumgardt (1950), Thomson (1949), Arden and Weale (1954) and many others. Of the various objections the most serious concerns the discrepancy between sensitivity changes and rhodopsin concentration. Granit and his associates (Granit, Holmberg and Zewi, 1938; Granit, Munsterhjelm and Zewi, 1939), were the first to show that large changes in the b-wave of the ERG in light and dark adaptation involve only very minor changes in the concentration of rhodopsin. According to their measurements, a large part of light and dark adaptation appeared to depend primarily upon the first fraction of rhodopsin to be bleached and the last to be resynthesized. They suggested that only a small fraction of the rhodopsin of a rod, probably concentrated at its surface, is directly involved in excitation and adaptation, the greater proportion representing a "store" from which the active surface material is replenished by diffusion (Granit, Holmberg and Zewi, 1938).

¹ The second equation was found less unsatisfactory than the first one.

Later Rose (1948) concluded that only a small fraction of the sensitivity changes occurring in light and dark adaptation can be ascribed to the capacity of visual pigments to absorb light, from his analysis of the behaviour of "ideal" picture pickup devices. Calculations by de Vries (1943), Baumgardt (1950) and Pirenne and Denton (1952), following the application of quantum theory to visual problems, also indicated that at moderate illuminations too little

FIG. 4.36. THE INDEPENDENCE OF THE TWO EYES IN REGARD TO DARK ADAPTATION AND THRESHOLD MEASUREMENTS

The determinations were made with the right eye while the left was frequently exposed to light, as indicated by the black marks. (Mandelbaum, 1941)

light reached the rods to produce sufficient bleaching of rhodopsin to accord with sensitivity changes. Experimental work by Hartline and his associates on light and dark adaptation in single receptors of the eye of *Limulus* indicates that although adaptation follows much the same course as in the vertebrate eye (Hartline and McDonald, 1947) little bleaching is apparently involved (Bliss, 1948).

Following the development of an ingenious technique for measuring the rhodopsin level in the living eye, Rushton and his collaborators have provided evidence that exposure of the human eye to a light which bleaches less than 2 per cent of its rhodopsin causes a fiftyfold increase in visual threshold, and at moderate room illuminations not more than 10 per cent of rhodopsin is bleached when equilibrium is reached. Following strong bleaching the subsequent return of the rhodopsin level to its full concentration follows an exponential curve with half-return constant of approximately 7 min. Rushton and Campbell (1954) conclude "that unless fairly bright photopic illumination is used, there is no appreciable change in the density of retinal rhodopsin."

In view of the above evidence it appears that a purely photochemical theory is no longer tenable,

even though Hecht's equations, as modified by Jahn (1946c) may still serve as a useful description of psychophysical data, so that the possibility of a neural component in adaptation should be considered. The question arises whether this component is central or peripheral (i.e. in the eye itself). Elsberg and Spotnitz (1938) claim that the central nervous system contributes to visual adaptation, citing evidence that adaptation of one eye affects the sensitivity of the other. Interocular effects of this kind have been claimed by several early authors although, as a review by Adams (1929) shows, opinions were divided on the subject. Helmholtz was one of those who held that the two eyes are independent.

The balance of evidence from the more carefully-controlled experiments is strongly in favour of Helmholtz's view. Mandelbaum (1941) could detect no difference between a dark-adaptation curve obtained in the normal way after light adaptation and another during which the opposite eye was exposed to a luminance of 6,000 mL through a 2-mm artificial pupil for several periods during the measurements (see Fig. 4.36). Crawford (1940) found no change in the value of the threshold energy of a fully dark-adapted eye when the light adaptation of the other eye was changed over a very wide range of intensities and the data of several other investigators support Helmholtz's opinion. It seems probable, as Crawford has suggested, that in experimental systems which have not employed Maxwellian view¹ some leakage of light may have occurred and affected the dark-adapted eye.

Although the matter is by no means settled (Wright (1946) for instance, has evidence to show that "adaptation of one eye can, under certain conditions, induce minor changes in the other"), the bulk of the evidence from interocular experiments is against Elsberg and Spotnitz's claim of a central component in adaptation (see also the later discussion of the effects of brain lesions).

Further support for the peripheral basis of adaptation comes from an experiment by Craik and Vernon (1941) in which they temporarily blinded one eye by applying pressure to the sclera. With a dark-adapted eye in this blinded condition they light-adapted it for three minutes to a luminance of 12,000 e.f.c. through a 2-mm pupil. At the end of light adaptation a dark adaptation curve was obtained from this eye. This curve was found to be the same as a curve obtained under similar conditions of light adaptation in a normal eye. The authors concluded that, "The normality of the dark adaptation curve obtained with an eye which has been blinded during the bright

¹ In the Maxwellian view (after the famous physicist, James Clerk Maxwell) an image of a light source is formed in the plane of the subject's pupil by means of a lens system. The method is frequently used in visual research where an extended test-field of high luminance is required.

adaptation period shows that light adaptation, both of rods and cones, is a retinal reduction of sensitivity and not a cortical one, since the primary stimulation never reached the higher centres."

From electrophysiological research comes further evidence in support of the peripheral nature of adaptation. The experiments already cited by Hartline¹ and MacDonald (1947) suggest that adaptation in man is determined in the retina while other evidence comes from studies of the ERG (Riggs, 1937; Wrede, 1937; Granit, 1947; Karpe and Tansley, 1948).

Accepting the evidence for the peripheral basis of dark adaptation and for a neural component, the question arises as to the nature of the neural mechanisms involved. Lythgoe (1940) suggested that a reorganization of neural connexions occurs during dark adaptation so that each fibre serves several elements by a spread of its synaptic connexions. The increased amount of convergence makes possible the integration of feeble light stimuli but at the same time there is a reduction in the eye's capacity for the finer discriminatory reactions which depend on the segregation of individual pathways. In other words, Lythgoe suggests that a type of "synaptic switching" occurs which has the effect of changing the properties of the retina from differentiating to integrative. A similar idea has been put forward by Adrian who considers that "... the interaction of nerve cells in the retina may change in degree or in sign, darkness favouring mutual summations over wider and wider areas" (Adrian, 1953, p. 110).

Although there is some evidence to show that the summation area increases during dark adaptation (Craik and Vernon, 1941; Arden and Weale, 1954) in the sense that an increase in area of test-field leads to a larger decrease in the value of the threshold energy in dark as compared with light adaptation, recent electrophysiological research by Barlow, Fitzhugh and Kuffler (1957) casts doubt upon Lythgoe's physiological speculations. Their work on changes in the organization of receptive fields suggests that although Lythgoe was correct in supposing that a change in retinal organization occurs in dark adaptation, he was doubly wrong on matters of detail. There appears to be a *decrease* rather than an increase in the degree of retinal interconnexion and the interconnexion which decreases is *inhibitory* rather than excitatory in type. However, in fairness to Lythgoe, it should perhaps be mentioned that he did seem to consider that part of the *initial* dark adaptation process must involve a recovery from inhibition for he regarded the uniformly-illuminated adapting-field as composed

of a "multitude of contiguous glare sources" each producing inhibitory effects in the manner of Schouten and Ornstein's alpha-adaptation (Schouten and Ornstein, 1939).

Although there is an accumulating body of evidence for a neural component in adaptation it is incorrect to conclude, as some authors have done, that adaptation is entirely neural. Under certain conditions there is a striking parallelism¹ between the course of bleaching and resynthesis of rhodopsin and the course of dark adaptation as pointed out by Wald *et al.* (1957). The relative contribution and the time course of the photochemical and neural components remain to be determined. So far there are no electrophysiological data on neural mechanisms that can be related quantitatively to psychophysical data on human dark adaptation.

ABNORMAL CONDITIONS

Studies of the effect of anoxia on dark adaptation have been undertaken by Tanaka and Sekiguchi (1935), Fischer and Jongbloed (1935), Bunge (1936), Clamann (1938), McFarland and Evans (1939), McDonald and Adler (1939) and McFarland and Forbes (1941). Controls in several of the earlier studies are unsatisfactory but are adequate in the 1939 and later experiments. McFarland and Evans (1939) measured dark adaptation in twenty subjects under reduced oxygen tensions, at simulated altitudes of 7,400, 11,000 and 15,000 ft. Fig. 4.37 shows the composite dark adaptation curve at each altitude and also the effects of giving oxygen at the end of the experiment. The effects of anoxia are to increase the threshold by 0.10 log unit at 7,400 ft, by 0.22 log unit at 11,000 ft and by 0.40 log unit at 15,000 ft. At the highest simulated altitude a light intensity about two and a half times the normal is required in order to be seen. There was a rapid return to normal sensitivity when oxygen was administered. Changes of a similar order were obtained by McDonald and Adler (1939); in their experiment anoxia caused an equal elevation of rod and cone thresholds.

One of the most interesting results of these experiments is that anoxia shifts the whole dark adaptation curve upward along the intensity axis without changing its shape. The effect is equivalent to placing a neutral density filter in front of the eye, a greater amount of light being required to produce a given visual response.

McFarland and Evans' results were confirmed in a later, better-controlled study, by McFarland and Forbes (1941) in which the Hecht-Shlaer adaptometer

¹ Hartline had shown earlier (Hartline, 1930) that in the eye of *Limulus* dark adaptation occurred according to a chemical reaction of a second order, this being consistent with photochemical concepts.

¹ Wald has quite recently claimed that not only is there a qualitative parallelism, but also a measure of quantitative agreement if changes in the *logarithm* of the visual sensitivity (i.e. $\log 1/\text{threshold}$) are compared with the rise of pigment concentration.

FIG. 4.37. THE EFFECT OF ANOXIA ON DARK ADAPTATION
(McFarland and Evans, 1939)

(Hecht and Shlaer, 1938) was used to measure dark adaptation and the effects of insulin hypoglycaemia were compared with those of anoxia. Following light adaptation to a large "white" adapting field of 35° angular diameter and 1,500 mL luminance for three minutes, thresholds were obtained for a 3' test-field situated 7° nasally in the right eye and exposed in 0.2 second flashes. The measuring light was from the extreme violet end of the spectrum.

Results for six practised subjects are shown in Fig. 4.38. The control curve is based on eighteen subjects. It will be seen that increasing degrees of anoxia cause an increased elevation of both rod and cone portions of the adaptation curve, the increase in threshold for 10.1 per cent oxygen being about 0.50 log unit for cones and 0.60 log unit for rods. The effects of insulin (5 to 8 units intramuscularly according to body weight) are shown in Fig. 4.39. Both control and

FIG. 4.38. MEAN DARK ADAPTATION CURVES SHOWING THE EFFECT OF LOW OXYGEN TENSION

In the control curves each solid circle is based on the average of eighteen experiments; in the curves obtained at simulated high altitudes, each open circle is based upon the average of six experiments.

(McFarland and Forbes, 1941)

FIG. 4.39. THE EFFECTS OF INSULIN, OXYGEN AND GLUCOSE ON LIGHT SENSITIVITY

The solid circles (control curve) are based on the average thresholds for nine subjects in air and the open circles for the same subjects also in normal air but after the injection of insulin, the inhalation of oxygen, and the ingestion of glucose. When the blood sugar was lowered by insulin the thresholds increased; when the subjects inhaled oxygen from a cylinder, the thresholds returned to normal; when the subjects were returned to room air the thresholds rose; and finally when the subjects ingested glucose the thresholds fell.

(McFarland and Forbes, 1941)

experimental curves are based on data for nine subjects. Insulin causes an upward displacement of the curve along the intensity axis by about 0.35 log unit.

Fig. 4.40 shows the combined effects of insulin and low oxygen for one subject. After obtaining a control curve the oxygen was reduced to 13.2 per cent and the subject was then given four units of insulin intramuscularly. Fifteen minutes later a dark adaptation curve was obtained again. The increase in threshold was about 0.6 log unit, a change much greater than a similar degree of anoxia or hypoglycaemia would have produced separately and somewhat greater than the sum of their separate effects.

Upward displacements, similar to those observed by McFarland and Evans (1939) and McFarland and Forbes (1941) in their duplex dark adaptation curves obtained from areas containing both rods and cones, have also been obtained in foveal dark adaptation curves by McFarland, Halperin and Niven (1944) and Hecht *et al.* (1946) (see Fig. 4.41).

Of a somewhat different nature from the experiments already discussed are several very important studies dealing with the effects of physiological stresses on the absolute threshold of the fully dark-adapted eye. McFarland and Forbes (1941) determined absolute thresholds for a 3° test-field situated

FIG. 4.40. THE COMBINED EFFECTS OF INSULIN AND LOW OXYGEN ON LIGHT SENSITIVITY

The solid circles (control curve) are based on measurements in normal air and the open circles in 13.2 per cent O_2 and after the injection of 4 units insulin. These effects were largely counteracted (as indicated by the triangles) when glucose was ingested, the oxygen remaining at 13.2 per cent.

(McFarland and Forbes, 1941)

7° nasally and exposed in 0.2 second flashes to the fully dark-adapted eye. As in the usual Hecht-Shlaer procedure (Hecht and Shlaer, 1938), the test-field was illuminated by light from the extreme violet end of the spectrum. Several experiments were carried out to compare the effects of anoxia and hypoglycaemia. Oxygen concentrations of 13.3, 11.4 and 10.0 per cent

caused an average increase of 0.19, 0.36 and 0.61 log unit, respectively, in a group of six thoroughly practised subjects. At the end of each test in low oxygen, subjects inhaled oxygen and, without exception, thresholds fell within two or three minutes to the normal level or even slightly below it. Changes in threshold could be detected after subjects had been inhaling oxygen for less than half a minute.

FIG. 4.41. EFFECT OF ANOXIA ON FOVEAL DARK ADAPTATION

(McFarland, Halperin and Niven, 1944)

In a second experiment McFarland and Forbes studied the effects of anoxia while the oxygen concentrations were gradually decreasing. After a steady threshold value had been attained following forty minutes' dark adaptation, the air in the experimental room was diluted with nitrogen so that within about twenty minutes the percentage of oxygen was reduced from 21 to 13 per cent. During the following hour the threshold was determined every two to three minutes as the oxygen was being reduced by a slow but continuous inflow of nitrogen. The final level averaged 10.2 per cent oxygen in experiments with five subjects and was lowered to 7.3 per cent for one subject. In each case the threshold rose as the oxygen concentration decreased, the average increase being about five-fold at 10.2 per cent oxygen. Fig. 4.42 shows the mean curve for five subjects. Inhalation of oxygen caused a return to somewhat better than normal sensitivity within two to three minutes.

In view of experiments in which improvement in visual sensitivity has continued for several hours (Semeonoff, 1941; Hume and Krebs, 1949) measurements of the effects of anoxia and breathing of pure oxygen may be subject to a certain amount of error due to changes in the "control" threshold values but the size of this error seems likely to be negligible in relation to the experimental effect. For the subject

who was exposed to an oxygen concentration of 7.3 per cent the threshold increase was about eightfold.

In a third experiment absolute thresholds were determined under normal conditions and then under anoxia. While the eyes remained in the dark-adapted state each subject drank a glassful of strong glucose solution (1 g glucose per kg body weight in 200 cc of water). Six to eight minutes elapsed while the glucose was being consumed and thresholds were then taken again in low oxygen.

"white" test-field, centred 13° below a red fixation point and exposed in flashes of one-fiftieth of a second. Observations were monocular through 1.6- or 2-mm artificial pupils in some of the experiments. These experiments were of two types, one in which the anoxia was of short duration and began and ended abruptly and another in which the anoxia was established gradually and maintained for several hours. Under the former conditions completely dark-adapted subjects, breathing through a mouthpiece,

FIG. 4.42 THE EFFECT ON LIGHT SENSITIVITY OF ALTERING THE PERCENTAGE OF OXYGEN IN THE INSPIRED AIR

After the eye was dark-adapted (control curve) for forty minutes, the air in the chamber was diluted with nitrogen. Then the thresholds, which were determined every two to three minutes, gradually rose as the concentration of oxygen was reduced. At the end of each experiment, the subject inhaled oxygen from a cylinder and the threshold returned to normal. The curves are based on the mean values of five subjects.

(McFarland and Forbes, 1941)

Following the ingestion of glucose the blood-sugar concentration, which averaged 65 mg per cent and remained fairly constant during the low oxygen tests rose to 128 mg and thresholds returned to normal within six to ten minutes.

McFarland and Forbes next studied the effects of insulin, oxygen and glucose on the absolute threshold in that order. After about forty minutes' dark adaptation when a steady threshold value had been obtained, subjects were given 5 to 8 units of insulin intramuscularly according to body weight and final rod thresholds were obtained after a further period of forty minutes' dark adaptation. Subjects then inhaled pure oxygen for six minutes, were suddenly changed back to normal room air and finally ingested 70 mg of glucose in 200 cc of water. The sequence of threshold changes is shown in Fig. 4.39. It is seen that the threshold increase due to insulin could be counteracted by the inhalation of pure oxygen. Subsequent breathing of room air caused an increase in threshold while glucose caused a fall in threshold.

In an investigation of respiratory effects upon the visual threshold Wald, Harper, Goodman and Krieger (1942) confirmed the findings of Bunge (1936), McDonald and Adler (1939) and McFarland and Forbes (1941) on anoxia. They used a circular 1°

were switched instantaneously from room air to air-nitrogen mixtures containing 8 to 11 per cent oxygen. After twenty to thirty minutes the subject was returned abruptly to room air.

The simplest and most usual type of response was for the threshold to rise within one to ten minutes of anoxia to levels 0.2 to 0.5 log unit above normal. In repeated experiments with six subjects this change averaged 0.35 log unit. On returning to room air the threshold usually fell within a few minutes to normal level. (Certain subjects gave results which departed from this pattern in various ways, due apparently to variations in breathing patterns. These variations were later made the subject of special study.)

A second type of experiment was carried out in a gas chamber in which the air was diluted with nitrogen without change in total barometric pressure. Oxygen contents of 11 to 12 per cent, simulating altitudes of 15,000 to 17,000 ft, were attained within thirty to ninety minutes after the first introduction of nitrogen. They were maintained for about five hours. Results showed an increase in visual threshold with the first dilution of oxygen. Data for one subject are shown in Fig. 4.43. As the authors point out, the form of the relationship suggests that with further decrease in oxygen tension the threshold might rise beyond the

maximum observed increase (0.35 log unit). However, the subject's behaviour indicated serious distress even at an 11 per cent oxygen level so that he probably could not have continued the experiment at lower oxygen pressures.

At the end of the experiment, after exposures of five, and six and a half hours to diminished oxygen tensions, the threshold returned to normal within five to six minutes. The magnitude of the changes observed in the long-term experiments agreed with those on sudden and short exposure to anoxia in the first experiment. Wald *et al.* comment on these results as follows: "The adjustment of central nervous structures to low oxygen tensions appears to be a rapid process. Anoxias of several hours' duration cause change in the threshold which neither exceed those recorded during the first few minutes nor persist longer after the return to room air" (Wald *et al.*, 1942, p. 897).

Wald *et al.* conducted further experiments on the effect of respiratory acid-base imbalance on the threshold. Subjects breathed to the beat of a metronome, as far as possible without change in amplitude and their rate and depth of respiration were recorded by pneumograph. For these experiments thresholds were measured in a 2° field centred 10° below the fixation point. Test flashes were of one-fiftieth of a second duration and 2-mm artificial pupils were used.

On increasing the rate of breathing room air by 50 to 100 per cent the threshold fell, within about five to ten minutes, to approximately half its normal value. In twenty-two experiments on two subjects the decrease ranged from 0.13 to 0.41 log unit and averaged 0.27 log unit (or a decrease of 47 per cent). Return to the normal threshold value occurred within two to three minutes. The increased sensitivity was not apparently due to increased oxygenation of the blood for oxygen tensions of 32 to 36 per cent did not appreciably affect the results. Instead it appears to be due to the alkalosis associated with hyperventilation. By adding carbon dioxide to the inspired gases it was possible to abolish or reverse the effect. The presence of 2 per cent carbon dioxide in mixtures containing 32 to 36 per cent oxygen did not affect the threshold when breathed at the normal rate but it completely abolished the decrease in threshold associated with rapid breathing. Increasing the carbon dioxide content to 5 per cent caused an increase of 0.2 to 0.5 log unit at both normal and rapid rates of ventilation. It appeared, therefore, that respiratory alkalosis and acidosis exert opposed effects upon the visual threshold, the former depresses and the latter raises the threshold by about equal amounts, averaging under the conditions of this experiment a factor of about 2.

Finally Wald *et al.* undertook experiments on the interaction of acid-base imbalance and anoxia upon

the threshold. As in the previous experiment, rate and depth of breathing were controlled and the test-field was viewed through an artificial pupil. The reaction to anoxia (10 per cent oxygen) was essentially similar to that observed in the first experiment (i.e. a doubling of threshold) but there was less individual variation due apparently to control of breathing. When oxygen was breathed at twice the normal rate a particularly interesting result occurred. Usually the threshold fell at first and always failed to rise for

FIG. 4.43 VARIATION OF ABSOLUTE THRESHOLD WITH DECREASE IN OXYGEN TENSION OR RISE IN SIMULATED ALTITUDE

Open circles, right eye, solid circles, left eye.
(Wald, Harper, Goodman and Krieger, 1942)

several minutes. Finally it rose to values above normal although it could remain below the level attained at lower rates of breathing. Effects of rapid breathing apparently at first predominated over the effects of simple anoxia but after a time some of this advantage was lost.

In a later experiment Alpern and Hendley (1952) studied the effect of variation in acid-base balance on the absolute threshold using the Hecht-Shlaer adaptometer. The test-field was situated 3° above the fovea (the size is not given) and exposed in 0.2-sec flashes, using the method of constants. Frequency-of-seeing curves were determined for eight subjects after thirty minutes' dark adaptation and the threshold determined by taking the intensity of retinal illumination at which the stimulus was seen 60 per cent of the time. Details of the method of producing metabolic and respiratory acidosis and alkalosis have already been given in the section on critical flicker frequency. As in the case of C.F.F., significant changes in threshold occurred only with respiratory alkalosis and acidosis, the former lowering, the latter raising it. The mean decrease amounted to 0.16 log unit and the increase was 0.23 log unit ($p < 0.001$). It is unfortunate that

the authors deal only with the effects on the statistically determined mean threshold value and do not present individual frequency-of-seeing curves.

In spite of several claims in the early literature (*see* Adams, 1929 for review) that the course of dark adaptation can be altered by the action of drugs,

Reviews of the literature by Rose and Schmidt (1947) and Segal (1953) provide further evidence of slight changes in threshold but very little indication of effects on the course of adaptation. However, the amount of well-controlled experimentation in this field is not yet large enough for final conclusions to be

FIG. 4.44. THE EFFECT OF DRUGS ON DARK ADAPTATION

Control curves are indicated by open circles and experimental curves by filled circles. A, 20 mg of amphetamine sulphate orally; B, 5 mg of strychnine sulphate subcutaneously; C, 0.5 g of caffeine with sodium benzoate subcutaneously; D, 20 mg of morphine sulphate subcutaneously; E 130 mg of phenobarbital orally; F, alcohol orally (whisky, equivalent to 180 cc of alcohol).

(Mandelbaum, 1941)

results of the more recent and carefully-controlled experiments are almost entirely negative. Using the Hecht-Shlaer adaptometer, Mandelbaum (1941) could detect no effect from strychnine, amphetamine, caffeine, phenobarbital, and morphine. Alcohol caused an increase of about 0.3 log unit in the final rod threshold and shifted the entire dark adaptation curve upward along the log-luminance axis but without changing its shape (*see* Fig. 4.44). The effects of alcohol are evidently similar to those of anoxia and insulin hypoglycaemia.

drawn. Apparently significant effects from caffeine (Segal, 1953) and amphetamine (Yudkin, 1941) on the cone-rod transition time, conflicting results on the effects of certain drugs (e.g. alcohol) and the insistence of Russian claims concerning the marked effects of sympathomimetic drugs¹ in increasing the rate of

¹ Marazzi (1943, 1953) found that adrenaline caused an inhibitory effect on the cat's optic cortex, and Rothan (1925) observed an increase in the visual threshold. Small increases in threshold have also been observed following the administration of ephedrine (Rose and Schmidt, 1947; Granger, 1954) but these were not statistically significant.

dark adaptation (Babskii, 1947; Babskii and Skulov, 1944) all indicate the need for further research. Investigation of the effect of various neurotropic drugs seems particularly necessary in view of the accumulating evidence for a neural component in adaptation.

Having considered the effects of physiological stresses and drugs it remains to consider the effects of various pathological conditions and "functional" disorders, in particular the condition known as night-blindness or nyctalopia in which vision at low intensities is poorer than normal. Known since ancient days it has for long been associated with deficient rod vision (Parinaud, 1881). It exists in two forms, one of which is inherited and the other associated with vitamin A deficiency. Dark adaptation curves for permanently night-blind individuals show only the initial cone drop in threshold with no secondary rod drop during the first hour of dark adaptation (Dieter, 1929; Takagi and Kawakami, 1924). Other data indicate that nyctalopes possess only one luminosity curve corresponding to the high intensity cone curve of normal individuals.

Literature on the acquired form of night-blindness, shown to be associated with a diet deficient in vitamin A as a result of the researches of Holm (1925), Tansley (1931), Fridericia and Holm (1925), is voluminous (*see*, for instance, Jeghers (1937) review) although the number of well-controlled experiments is relatively small. Mention can be made here of only one of these, a study by Hecht and Mandelbaum (1939) in which the dark adaptation of seventeen subjects maintained on controlled vitamin-A-deficient diets was measured at frequent intervals. Following light adaptation to 1,500 m^l for three minutes, thresholds were obtained for a 3' diameter field situated 7° nasally and exposed in 0.2 second flashes of "violet" light. Under conditions of vitamin A deficiency both cone and rod portions of the adaptation curve were displaced upward along the intensity axis although the general form of the curves remained the same. Fourteen out of seventeen subjects responded with an immediate increase in threshold which continued for the duration of the diet but the remaining three subjects required twenty-two, fifty-five and sixty days before showing a definite and continuous increase in threshold. Partial recovery was effected in some cases by giving single large doses of vitamin A but permanent recovery was slow, often requiring several months.

In a useful review, Sheard (1944) points out that in addition to inadequate intake of vitamin A, there are numerous conditions which can lead to a deficiency. "Fever, general infection, rapid growth, elevated basal metabolic rate, pregnancy, lack of bile or pancreatic secretions, changes in the gastro-intestinal tract, or hepatic disease may prevent or hinder the proper

absorption or storage of vitamin A." Cirrhosis of the liver is a good example of the operation of an aberrant factor in vitamin A metabolism and Haig, Hecht and Patek (1938) have provided data from fourteen patients suffering from this condition. They used a light-adapting field of 1,600 m^l of four minutes' duration and obtained thresholds for a 4.5° diameter field situated 8.5° nasally in the right eye, and exposed in 0.2 second "violet" flashes. Thirteen subjects

FIG. 4.45 THE DARK ADAPTION OF A PATIENT WITH ALCOHOLIC CIRRHOSIS OF THE LIVER DETERMINED AT DIFFERENT TIMES DURING VITAMIN A THERAPY

Curve A was obtained when the subject was on an ordinary diet; curves B and C were obtained after one hundred and five and one hundred and twenty-seven days, respectively, of vitamin A therapy. Measurements were made using a "violet" test light; those denoted by filled circles indicate that the light was seen as coloured, those shown as open circles were made when the light appeared colourless.

(Haig, Hecht and Patek, 1938)

showed a disturbance of dark adaptation. An interesting feature of the illustrative data shown in Fig. 4.45 is the decrease in cone-rod transition time, which occurred following a course of vitamin A therapy, as compared with its stationary position in experiments on dietary avitaminosis (Hecht and Mandelbaum, 1939).

The individual differences in response to vitamin-A-deficient diets observed in Hecht and Mandelbaum's experiment is a common feature of investigations of nutritional night-blindness, as is the marked variation in the time taken for recovery in patients undergoing vitamin A therapy. These two inconsistencies, which puzzled some of the early investigators, have been considerably clarified as a result of recent research. The first seems at least partially explicable in terms of the large individual variations in the amount of vitamin A stored in the liver. What appears to happen is that so long as stores of vitamin A remain in the liver, the blood vitamin A level is maintained above a certain value (about 50 I.U. per 100 ml of serum) and vision remains normal. When the liver stores become exhausted the blood level falls and the individual

begins to show symptoms of night-blindness (Hume and Krebs, 1949; Moore, 1953).

Clarification of the second inconsistency results from a study by Dowling and Wald (1958) who have also made a major contribution to our understanding of the aetiology of night-blindness. By determining simultaneously the vitamin A content of the liver, the vitamin A of the blood plasma, the concentration of rhodopsin and of opsin (an additional component of

FIG. 4.46. MEAN DARK ADAPTATION CURVES OF TWENTY NORMAL AND TWENTY PSYCHIATRIC PATIENTS

Open circles denote psychiatric patients; filled-in circles denote normal subjects.

(Granger, 1957)

the visual pigments) in the retinæ of rats kept on a vitamin-A-deficient diet, and recording ERG changes, they were able to present a clear and simple picture of the rise and fall of the disease. After vitamin A has left the blood due to depletion of the liver stores the retina is apparently no longer able to obtain sufficient vitamin A to occupy all its opsin, lower than normal amounts of rhodopsin are formed, and night-blindness ensues. At this stage when the retina contains all its opsin but insufficient supplies of vitamin A, it is possible to cure night-blindness very rapidly. By administering vitamin A as quickly as it can be acquired by the retina, rhodopsin is restored to its normal level and night-blindness ends. However, with further development of the deficiency the concentration of opsin itself begins to drop and at this stage anatomical deterioration of other tissues in the eye and elsewhere begins to occur. Under these conditions recovery from deficiency is much slower for time must be allowed for the structural repair of the eye tissues before a normal visual threshold can be obtained. Although their experiment was done on rats it seems probable that human night-blindness depends on very similar relationships.

Because the vitamin A studies represent an outstanding scientific contribution in which psychophysical measurements have figured prominently it seems necessary to say something briefly about their physiological and practical significance before going on to discuss other abnormal conditions. From a physiological point of view not only have they helped to elucidate the role of vitamin A in the biochemistry of visual excitation but they have also served to link the relatively isolated study of visual processes with the more general metabolism of vitamin A throughout the body and thus helped to make explicit some of the general "conditions of the organism" that affect visual response (see Graham's equation, page 108). From a practical viewpoint they provide an excellent example of the experimental investigation of the aetiology and therapy of a human deficiency disease.

The influence of various pathological conditions, including retinitis pigmentosa, glaucoma, syphilitic atrophy of the optic nerve and renal lithiasis, has been considered by Mandelbaum (1941). In none of these conditions is the rate of adaptation affected. Retinitis pigmentosa has an effect on the curve of rod adaptation, rod function becoming increasingly impaired until it apparently disappears completely leaving a cone curve of normal shape but situated at a higher intensity level. The same upward shift of the dark adaptation curve appears to a lesser extent in advanced glaucoma, optic nerve atrophy and the other disease conditions.

Clinical studies of dark adaptation curves in various types of brain lesion have been carried out by Ullrich (1943), Ruesch (1944), Krieger and Bender (1949, 1951) and Bender and Krieger (1951). All these authors claim various anomalies in threshold and in the course of dark adaptation but they do not provide sufficient information about experimental conditions and results for their conclusions to be assessed. Of the various studies Krieger and Bender's is the most suggestive for further research. It suggests, as would be expected, that lesions to the visual pathway beyond the retina result in raised thresholds. But although the authors claim that the rate of adaptation is affected, none of their published curves supports this claim. The threshold increases they observed can be accounted for in terms of a conduction block. It appears, however, that they have collected a large amount of unpublished data in which changes occurred in the shape of dark adaptation curves. Repetition of the experiment seems desirable.

Following a wartime observation that the incidence of "night-blindness" appeared to be higher among neurotics than among normal Service personnel, several studies have been undertaken in which the night-vision efficiency and dark adaptation of normal and psychiatric groups has been investigated. Results

indicate (Granger, 1957a) that psychiatric disorder has no effect on the course of dark adaptation although there is a tendency for changes in threshold to occur with upward displacement of the entire "rod" dark adaptation curve along the intensity axis (Fig. 4.46).

IV. PSYCHOPHYSICAL AND PHYSIOLOGICAL ANALYSIS OF STRESS EFFECTS

In view of their scope and the precise theoretical treatment of the data the studies of anoxia provide a convenient starting point for discussing mechanisms underlying the effects of physiological stresses. The most striking result of these studies is that anoxia does not apparently change the shape of the cone and rod dark adaptation curve or the curves relating brightness discrimination and visual acuity to illumination but merely affects their position on the intensity axis. The curves relating acuity and brightness discrimination to intensity are displaced to the right on the intensity axis while dark adaptation curves are displaced upward. If the absolute threshold for the dark-adapted eye is considered as the limiting value of the differential threshold when the field intensity is zero (McFarland, Halperin and Niven, 1944) the effects of anoxia on the absolute threshold can be shown to be similar both in direction and magnitude to the effect on intensity discrimination.

In all these experiments the effect of anoxia is, as McFarland *et al.* (1944) have pointed out, equivalent to placing a neutral density filter in front of the subject's eyes, a greater intensity of illumination being necessary to produce a given response. The analogy of the optical filter was current in Hecht's laboratory before the last war and "seems to have been shared by a number of other biologists" (Pirenne, Marriott and O'Doherty, 1957). Its application to "normal" data is nicely illustrated by a hypothesis suggested by Pirenne *et al.* (1957) in their research on "Individual differences in Night-vision Efficiency," referred to earlier in the chapter. With a view to accounting for individual variation in acuity and at the same time the general similarity in shape of log-acuity/log-luminance curves these authors put forward a "filter factor" hypothesis. The term *filter factor*¹ is used on analogy with the photographic filter factor which concerns the lengthening of exposure which becomes necessary when a given colour filter is used in a camera. In its simplest form the "filter factor" hypothesis "assumes that a subject A, behaves as if he had the same eyes, brain, mind, etc., as a subject B, but had in front of these eyes light filters of trans-

Unfortunately the measurements are subject to some of the errors of the type discussed on page 137 so that one cannot conclude with any certainty that the absolute threshold is higher than normal (Granger, 1957b).

mission $1/k$, the value k being the filter factor. According to this hypothesis A would always need k times more *external* light than B to perform any given visual task" (Pirenne *et al.*, op. cit., p. 27, 1957).

Applying this hypothesis to the acuity data in Fig. 4.12, A's and B's curves would be of the same shape

FIG. 4.47. DIAGRAM TO ILLUSTRATE THE FILTER FACTOR HYPOTHESIS

Subject A has the same acuity as subject B provided the luminance is multiplied by a constant factor k at all levels. The vertical lines indicate the variations of acuity at two fixed luminance levels (Pirenne, Marriott and O'Doherty, 1957)

but A's curve would be shifted horizontally as a whole to higher luminances by an amount equal to $\log k$, i.e. to the optical density¹ of the hypothetical filter. This horizontal shift is illustrated in Fig. 4.47 which gives curves for subjects A and B similar to the experimental curves of Fig. 4.12.

The hypothesis accounts for the experimental data in the range corresponding to rod vision; at the highest acuity and luminance levels, where acuity becomes constant and independent of luminance level the hypothesis has no meaning, as its authors point out. The predictive value of the hypothesis was tested in a further experiment on "perceptual efficiency" in

¹ Pirenne *et al.* point out that their use of the term *filter factor* probably originates from a report by Hartline and McDonald (1957). They also point out that, unlike the photographic filter factor which refers to change in exposure time, their filter factor refers to changes in light intensity.

¹ The optical density is defined as the negative logarithm, to base 10, of the fraction of light transmitted. Density = $\log \frac{I}{I_t}$, I being the incident light intensity and I_t the intensity transmitted.

which subjects were asked to perform a complex perceptual task (perceiving details in a Hogarth print) under conditions of low illumination. The authors were able to show that when the illumination falling on the picture was adjusted in accordance with the individual "filter factors," determined from their absolute thresholds in an earlier experiment, individual variation was almost completely eliminated.

As used by Pirenne *et al.* (cf. Hartline and McDonald, 1957; Hecht and Pirenne, 1940) the "filter factor" serves as a convenient "physical" descriptive device which leads to a number of predictions at the psychophysical level. However, it is also of interest to consider the possible physiological basis of the hypothetical filter in specific instances. An attempt has been made to do this by Hecht *et al.* (1946) in the case of anoxia experiments although these authors make no explicit reference to the filter factor analogy. Seeking a physiological basis for the effect of anoxia on brightness discrimination they propose a formulation in terms of Hecht's stationary state equation.

They point out that when setting up equations for the primary light and dark reactions Hecht (1937) introduced the fewest components required for quantitative description and explanation. In consequence, the stationary state equation involves light intensity and concentration "with only the most necessary constants to connect them with known chemical and physical laws." But the data of visual experiments refer not to concentrations of sensitive materials but to properties of the visual system which express neural activity resulting from the transformation of visual pigments. It becomes necessary, therefore, to formulate explicitly the relation between photochemically effective light and magnitude of visual function. In the earlier formulation Hecht (1937) assumed a one-to-one relation and included it in the constant k_1 (see page 118) but although this may be satisfactory for "normal" physiological conditions of the organism, abnormal conditions such as anoxia demand a more explicit consideration of the relation.

Hecht *et al.* then proceed to modify the original equations by introducing a factor α which, although they do not describe it thus, may be regarded as the physiological counterpart of the filter factor. "The simplest meaning to attach to α is that of a linear conversion factor from light absorbed to number of impulses leaving the particular sense organ, or ultimately reaching the cortex."

It is then possible to consider not merely the rate of photochemical change as in the original equations but the magnitude of the neural counterpart of the photochemical change. Hecht *et al.* write—

$$di/dt = \alpha dx/dt = \alpha k_1 I(a - x)^m \quad (3a)$$

as representing the rate of impulse production i during

the stationary state. The stationary state equation itself becomes—

$$\alpha k_1 I/k_2 = x^n/(a - x)^m \quad (5a)$$

Under abnormal physiological conditions, such as anoxia, the conversion factor α which is normally constant and with k_1 forms a single constant, changes even though k_1 and k_2 may remain constant. Hecht *et al.* assume that α must become smaller under oxygen lack so that the same chemical change $k_1 I(a - x)^m$ will now produce a smaller effect in terms of *visual* function because it is multiplied by a smaller α .

Taking into account the conversion factor, the original equation (6), describing the increase in photochemical change which occurs when the intensity increment ΔI is added to the field intensity I , now becomes—

$$di/dt = \alpha k_1 \Delta I(a - x)^m \quad (17)$$

which describes the *neural effectiveness* of the photochemical change, ΔI will now equal $c'/\alpha k_1(a - x)^m$ and equation (9), which is the appropriate equation for cone vision becomes—

$$\Delta I/I = C \left[1 + \frac{1}{(\alpha KI)^{\frac{1}{n}}} \right]^2 \quad (18)$$

where $C = c/a^2 k_2$.

Plotted on a double logarithmic grid, the shape of the curve of equation (18) is constant and independent of C and αK which locate its position on the ordinate and abscissa, respectively. The experimental data indicate that anoxia affects neither the shape of the curve nor its position on the ordinate so that C is unchanged. Either α or K must be altered for the curve is shifted along the intensity axis to higher intensities.

Hecht *et al.* consider that as the constant C is not altered by anoxia, its components are also unchanged (it would be unlikely that a change in the numerator were balanced by a similar change in the denominator). Considering next the constant K , it seems unlikely that it is altered for it equals k_1/k_2 , and k_1 has the dimensions of absorption (Hecht, 1924) and does not change with temperature or oxygen (Hecht, 1924b; Bruner and Kleinau, 1936; Chase and Hagan, 1943) while, from the previous argument, it appears that k_2 is unaltered. This leaves α as the only parameter likely to be affected.

From the data it is possible to determine how the conversion factor α varies with oxygen concentration, by considering the horizontal displacement along the $\log I$ axis for different concentrations. A constant $\Delta I/I$ requires αKI to be constant (from equation 18); since anoxia shifts the curve, increasing I , α must vary inversely with the intensity increment. Assuming α has a value of 1 at sea level (i.e. under "normal"

physiological conditions) its value for any other oxygen concentration can be computed from the magnitude of the log I shift (log α will be 0 minus the increase in log I for a given concentration).

The relation between oxygen concentration and the conversion factor is shown in Fig. 4.48; at low oxygen concentrations the curve is steep and flattens out as sea level values are approached. Particularly interesting is Fig. 4.49 which shows the relation between the oxygen saturation of the blood and the intensity shift of the $\Delta I/I$ curve. (The saturation values represent average arterial saturation taken from the *Handbook of Respiratory Data in Aviation* (see Hecht *et al.* for reference, 1946). The straight line through the points has a slope of 4 so that the conversion factor α , corresponding to the log I shift, varies as the fourth power of the arterial saturation. As the authors rightly point out, much more knowledge about oxygen action is required before this relation can have much meaning but it is clear that relatively slight changes in oxygen saturation produce large changes in differential threshold. The interpretation which Hecht *et al.* suggest for the shift of the intensity discrimination curve can also be applied to McFarland,

Fig. 4.48. RELATION BETWEEN OXYGEN CONCENTRATION AND THE CONVERSION FACTOR α WHICH "TRANSLATES" CHEMICAL CHANGE INTO PHYSIOLOGICAL MAGNITUDE"

The value of α is assumed unity at sea level.
(Hecht, Hendley, Frank and Haig, 1946)

Halperin and Niven's (1944) data and those of McFarland and Evans (1939).

Hecht *et al.* suggest that the "conversion factor" has a retinal locus, probably in the bipolar and ganglion cells. The reasons they provide for supposing that changes occur in the retina rather than the central nervous system are, first, the retina has a very high oxygen requirement, the highest rate of any tissue recorded by Warburg (1927) and, second,

"when flyers are subjected to centrifugal forces several times gravity they become temporarily blind before they become unconscious." The second of these reasons is less convincing than the first for there seems no reason why the visual cortex should not be affected before the brain centres associated with consciousness.

Available evidence indicates that Hecht *et al.* are correct in supposing that photochemical mechanisms are not involved but wrong in their emphasis on the

FIG. 4.49. THE RELATION BETWEEN OXYGEN SATURATION OF THE BLOOD AND THE INTENSITY SHIFT OF THE $\Delta I/I$ CURVE
(Hecht, Hendley, Frank and Haig, 1946)

exclusive role of the retina. The following considerations support a non-photochemical basis for the effect of anoxia. First, anoxia depresses sensitivity in the fully dark-adapted eye when regeneration of rhodopsin should be complete (Wald *et al.*, 1942). Second, anoxia produces an equal increase in cone and rod thresholds although different pigments are involved (McFarland and Forbes, 1941). Third, the rate of improvement in sensitivity when oxygen is reintroduced is too rapid to be explicable in terms of pigment regeneration (McFarland and Evans, 1939). Fourth, Vishnevskiy and Tsyrlin (1936) found that lowered atmospheric pressure caused a decrease in the electrical excitability of the eye as well as in its light sensitivity even though in the former case the photochemical system was by-passed.

That the retina itself may be affected, in accordance with Hecht's assumption, is shown by the results of experiments by Seitz (1940) and Seitz and Rosenthal (1941) who found that local application of strychnine to the conjunctiva counteracted the effects of anoxia on visual C.F.F. and the angioscotoma whereas no such changes occurred in the untreated eye. But evidence for the involvement of extra-retinal mechanisms comes from several sources. Clamann (1938) on the basis of limited data, suggested that central processes must participate because monocular thresholds were affected differently from binocular thresholds in his study of dark adaptation. Gellhorn

and Hailman (1944) found that changes in visual C.F.F. were paralleled by typical anoxic changes in the brain, as evidenced by EEG records. The primary importance of the visual cortex is suggested by the electrophysiological observations of Noell and Chinn (1950) who found that inexcitability occurs in the visual system of the rabbit, under anoxia, in the following order: cerebral cortex, lateral geniculate bodies, retinal ganglion cells, retinal bipolar cells, and, lastly, the receptors.

In view of these considerations and the earlier criticisms of photochemical theory, the factor α can hardly be termed a conversion factor in the sense that it "converts" chemically-effective light into "impulses leaving the sense organ." A better term might be "central effectiveness" constant (cf. McFarland, Halperin and Niven, 1946), implying that it determines the central effectiveness of changes induced in the peripheral (photochemical and neural) mechanisms involved in reception.

The filter factor hypothesis and the above analysis also seem applicable to the effects of insulin hypoglycaemia on brightness discrimination and dark adaptation. There is, in fact, some reason to suppose that both conditions may produce their effect in the same way, by slowing the oxidative processes (McFarland *et al.*, 1946). Results of studies by Himwich and Fazekas (1937), Himwich, Frostig *et al.* (1939), Himwich, Hadidian *et al.* (1939), and many others indicate that as the blood glucose is decreased by insulin the oxygen consumption of the brain declines along with its glucose utilization. McFarland *et al.* (1946) have pointed to a strong parallelism between changes in the occipital potentials occurring during insulin hypoglycaemia and effects on visual thresholds. Brazier *et al.* (1944) found that blood-sugar levels below 70 mg per 100 ml, but not sufficiently low to impair consciousness, produced slowing of the dominant frequency and development of activity slower than alpha. The data of McFarland *et al.* (1946) show visual effects at blood-sugar levels below 65–70 mg per 100 ml. High blood-sugar levels (above 130 mg per 100 ml) did not affect the EEG nor did they affect visual thresholds. Gellhorn and Kessler (1942) found, in accordance with the visual data, that the EEG changes induced by insulin hypoglycaemia could be off-set by inhaling pure oxygen. Himwich, Hadidian *et al.* (1939) found that EEG changes tended to lag behind the blood-sugar curve, a result paralleled by the occurrence of the maximum visual effect in McFarland, Halperin and Niven's experiments at a later stage than the minimum blood-sugar level. That insulin must exert its effect through central nervous metabolism rather than on the photochemical system of the eye is indicated by the lack of evidence that the breakdown of visual pigments involves glucose, as

well as by the changes induced in the fully dark-adapted eye.

Data on the effects of respiratory acidosis and alkalosis on the absolute threshold (Wald *et al.*, 1942; Alpern and Hendley, 1952) may also be described in terms of the filter factor analogy, the former condition resulting in a high value of the filter factor and the latter condition in a low value. Alpern and Hendley¹ (1952) have attempted an explanation of their data at the photoreceptor level in terms of Fry and Alpern's (1946) extension of Jahn's (1946a, b, c) photochemical theory but other evidence suggests that changes occur central to the photoreceptors. Thus Dusser de Barenne, McCulloch and Nims (1937) showed in the cat that hyperventilation increased the pH of the cerebral cortex and simultaneously lowered its threshold for neural and electrical excitation while hypoventilation raised the threshold. Analogous results have been obtained with peripheral nerve (Lehmann, 1937).

Other data to which the filter factor analogy seems applicable include those from experiments on the effects of various pathological conditions (summarized by Mandelbaum, 1941), brain lesions, alcohol and, possibly, psychiatric disorders on the visual threshold and dark adaptation. In all these cases the psychophysical effect is the same and consists of an upward displacement of the adaptation curve along the intensity axis, although different physiological mechanisms may be involved. What these are can only be decided by further experiment. In the case of alcohol the mechanisms may be similar to those involved in anoxia, for there is some evidence that alcoholism is a form of anoxia (histotoxic) and that the tissue cells are poisoned in such a manner that they cannot use oxygen properly. Similar mechanisms may also be involved in the case of certain psychiatric disorders, such as schizophrenia in which oxygen deficiency has been reported from time to time (cf. McFarland, 1952) but the evidence for either raised visual thresholds or impaired oxidation in schizophrenia is far from satisfactory.

Although the analogy of the filter factor seems applicable to the effects of several different types of abnormal conditions, as well as to normal variation (e.g. Pirenne *et al.*, 1957; Hecht, Haig and Chase, 1937) its precise scope is difficult to determine in certain cases owing to lack of experimental data covering a sufficiently wide range of stimulus intensities. This is true of studies on the effects of certain physiological stresses and drugs on C.F.F. The data in Seitz's (1940) study of anoxia, for instance, are too limited to decide whether anoxia causes a shift in the F -log I curve along the intensity axis or along both

¹ Changes in the ERG during hyperventilation have been reported by Dodt (1951b) and Alpern *et al.* (1955).

axes. The upward displacement along the intensity axis of the entire dark adaptation curve by alcohol suggests that this drug may affect the F -log I curve in the same way. Goldberg (1943) has in fact described its effect in terms of the filter analogy but the experimental data are not sufficiently extensive to demonstrate this. More psychophysical data seem particularly desirable in the case of this drug for it has the interesting property of selectively blocking inhibition in the eye. Bernhard and Skoglund (1941) demonstrated this on the negative PIII component of the ERG and the "off" response from the frog's eye and suggested that this might be the mechanism underlying the drug's depressant action on sensory C.F.F. Bernhard (1941) found that the practically pure negative response of the cone eye of the tortoise (*Testudo graeca*) was also suppressed by alcohol and later studies by MacNichol and Benolken (1956) have shown that alcohol causes a blocking effect on inhibitory synapses in the lateral eye of *Limulus*. A further study which bears on the interpretation of C.F.F. changes is that of Svaetichin (1956) who found that a drop of diluted ethyl alcohol instilled into the fish retina lengthened the rise and decay times of the cone action potential. In spite of these results there is no reason to suppose that the effects of alcohol are exclusively on the retina. In fact the drug's depressant action on the absolute threshold during dark adaptation suggests that more central mechanisms may be affected for on the basis of Bernhard and Skoglund's results one might expect alcohol to lower the absolute threshold. The changes induced in the ERG by alcohol were essentially similar to those produced by dark adaptation. The depressant action of the drug at different levels might account for some of the discrepant findings reported in the literature.

Data which seem unlikely to be capable of description in terms of the filter factor analogy are those of Alpern and Hendley (1952)¹ on the effects of hyperventilation on C.F.F. for their curves suggest a "change in maximum discriminatory ability, rather than a shift to a higher or lower light level," even though they are based on very few experimental points. In spite of the limitations of the filter factor analogy it is interesting to note that neither anoxia nor hyperventilation affects the shape of the curve relating C.F.F. to intensity; only the dimensional constants appear to be changed. Taking into account the physiological data on the peripheral determination of dark adaptation and the curves showing the relation between the various differential thresholds and illumination the following generalization is suggested.

Physiological stresses, drugs and other abnormal conditions do not affect the basic S-R relations through the receptor systems but merely alter the extraneous constants of those relations (cf. earlier discussion of the effects of area, page 127). Although visual thresholds (absolute and differential) are sensitive to various kinds of "physiological imbalance," functions such as dark adaptation and the improvement in discrimination which occurs when the illumination is increased, appear to be highly resistant to such changes. For instance, although under conditions of anoxia a threefold increase in the visual threshold can occur, the course of dark adaptation remains unaffected. The magnitude of the change induced by such a severe physiological stress, which is probably close to the limits of variation that can be expected from changes occurring in the central nervous system, is negligible in relation to the range of intensities covered in a typical dark adaptation experiment ($1:10^6$) or the total range of intensities over which the eye can function ($1:10^{15}$).

However, even though the effects of anoxia and (what sensory physiologists are apt to call) other "special" conditions (cf. Wald, 1954) such as acidosis and alkalosis, are of only secondary importance to a physiology of the special senses concerned to explain the shape of dark adaptation curves or the relation between the incremental threshold and field intensity, the fact remains that fluctuations in visual thresholds can be induced by changes occurring in neural structures in the retina and central nervous system. Measurement and analysis of this variation by psychophysical and physiological methods is obviously necessary for a complete understanding of the visual process.

Analysis of threshold variation is important also from a broader viewpoint than that of Visual Physiology for, as Gellhorn has pointed out, the "sense organs (including the visual system) represent natural avenues of approach to the central nervous system" (Gellhorn, 1942). It was from this point of view that Cajal (1894) made his histological studies of the retina and Granit (1947) studied retinal physiology. The investigations of the effects of physiological stresses reviewed in this chapter have shown how psychophysical experiments on visual thresholds can reveal some of the fundamental metabolic characteristics of the central nervous system (cf. Gellhorn, 1942).

One of the chief reasons for the significance of visual threshold measurements arises from their sensitivity. Whereas it was formerly supposed that oxygen deprivation caused impairment only at high altitudes, visual thresholds revealed marked changes under relatively minor degrees of anoxia. In this respect they are more sensitive than tests of other sensory functions such as audition and some of the

¹ The recent measurements of Granger and Ikeda (1959a) certainly cannot be explained in terms of a simple filter factor hypothesis.

"higher" mental functions (McFarland, 1952). The further advantages of visual thresholds over other forms of psychophysiological test, which were pointed out by McFarland, Halperin and Niven (1944), are their independence of the effects of masking due to the subject's exerting additional effort, and their stability during control experiments when the physiological stresses are not applied and the precision with

which the physical measurements can be made. Taking into account the results of their experiments on the absolute threshold Wald *et al.* (1942) considered that its advantage over other types of physiological measurement was that "it provides an index of net change in the central nervous system, usually the first to fail in physiological stress" (1942, p. 901).

V. IMPLICATIONS FOR OTHER ABNORMAL CONDITIONS

As one approach to the investigation of C.N.S. excitability and stresses involving the central nervous system, the measurement of visual functions already has a wide field of applications in medicine, as the clinical studies reviewed in this chapter have clearly shown. Significant changes in visual thresholds have been observed in metabolic disorders, diseases of the respiratory system, diseases of the blood, endocrine disorders, various intoxications, and disorders of the nervous system. Even though actual data are in certain cases available for only a few specific disorders in each of these areas, these data considered in relation to the studies of physiological stresses and drugs have implications for a variety of other pathological conditions. Changes in visual thresholds similar to those occurring in the experiments on anoxia would, for instance, be expected in a number of clinical disorders in which anoxia occurs in one of its several different forms. Any condition which results in mechanical interference with oxygen absorption, such as pneumonia, pulmonary oedema, pulmonary congestion, bronchial asthma and acute bronchitis, might produce measurable changes consequent to anoxic anoxia. Similarly the depression of visual sensitivity observed in anaemia would be expected to occur also in other conditions which lead to a diminution in the oxygen capacity of arterial blood due to a reduction in the amount of functioning haemoglobin. The decrease in C.F.F. found in circulatory failure associated with decompensated heart disease (Enzer, Simonson and Blankstein, 1942) might also be predicted to occur in conditions associated with vagoplastic phenomena such as Raynaud's disease, due to circulatory insufficiency and consequent "stagnant anoxia." Finally, any condition interfering with oxygen utilization by the tissues due to the poisoning of the tissue cells would be expected to have visual effects similar in part to those of alcohol.

The studies of insulin hypoglycaemia also have implications for various pathological conditions in which hypoglycaemia occurs, such as hepatic disease, adrenal cortical insufficiency, anterior pituitary insufficiency, various disorders of the central nervous system and miscellaneous conditions accompanied by severe grades of undernutrition, such as *anorexia*

nervosa. Studies of hyperventilation have implications for many clinical conditions in which respiratory alkalosis occurs such as certain cases of encephalitis manifesting hyperpnoea over prolonged periods of time, fever (where hyperventilation can occur as a result of increased respiratory rate) and, possibly, hysteria, while the studies of respiratory acidosis have implications for clinical conditions in which the elimination of CO₂ through the lungs is retarded, as in pulmonary fibrosis. Even the very limited data on dehydration may have implications for conditions in which excessive loss of one or more of the body secretions or excretions occurs. Effects of these various stresses are not of course independent of one another, dehydration leading to a change in acid-base balance, etc.

Obvious implications for the study of psychotic and neurotic disorders (conditions of special interest to the practising clinical psychologist) arise from the experiments on stresses and drugs although these are clearer for the psychoses associated with metabolic, cardiovascular and endocrine disorders and intoxications than for the so-called "functional" psychoses and neuroses. Deviations from normal threshold values might be expected to occur in a wide variety of psychiatric patients suffering from functional disorders, in schizophrenics showing signs of oxygen deficiency (McFarland, 1952), in neurotics or psychotics with very high or very low "sedation thresholds" (Shagass and Naiman, 1955, 1956), in the so-called "cardiac" neuroses, and in "aeroneuroses" with symptoms of fatigue and exhaustion (Armstrong, 1936; Krugman, 1947), in severe anxiety attacks associated with the liberation of adrenalin into the blood stream (cf. studies of sympathomimetic drugs, page 133), and numerous other conditions. Available physiological and biochemical data do not, however, allow specific predictions to be made about *all* patients classified by psychiatrists into the general categories of schizophrenia, hysteria, anxiety state, etc., owing to the heterogeneity of physiological reactions within these groups.

Although there can be no doubt that the measurement of visual functions has a wide field of potential applications in psychiatry, neurology and other

branches of medicine the fact that threshold variations are not specifically related to any particular abnormal condition means that in clinical applications "caution in the interpretation of results is necessary and, as a rule, additional information obtained by independent methods is desirable for more specific correlations" (Simonson and Brozek, 1952). To this cautionary note may be added the further requirement that experimental conditions in clinical research must be specified and controlled as carefully as is customary in Visual Psychophysics if data are to be reproducible and have unambiguous meaning in sensory terms. The need for precise controls is particularly important for the magnitude of the threshold changes induced by variations in the state of the central nervous system seem likely in many cases to be small in relation to other sources of variation.

The formidable array of requirements which sensory psychologists and physiologists consider must be met before psychophysical functions can be properly measured may seem to some clinical psychologists to introduce unnecessary complications into testing procedures. In fact, they serve to simplify description and

analysis, as Mandelbaum has pointed out in a discussion of Hecht's rather elaborate "fixation-and-flash" method for measuring dark adaptation: "One of the first principles in investigation is to isolate carefully the phenomenon being studied in order to remove as many extraneous influences as possible. If this procedure can be followed the results obtained are physiologically simple, for they describe the isolated phenomenon and are most readily capable of simple physiologic interpretation. However, simplicity in procedure—in this case inadequacy in the apparatus used and failure to meet the specifications to be outlined—can produce only the opposite effect. The no longer relatively isolated phenomenon of dark adaptation is obscured in a maze of complexities brought on by inadequate retinal fixation, altering color temperatures of the test light and many other uncontrolled factors" (Mandelbaum, 1941, p. 204). It is for this reason that those data on vitamin A deficiency and dark adaptation which have been obtained from "simple" and "rapid" tests have proved to be so unreliable and led to so much confusion regarding their interpretation.

VI. IMPLICATIONS FOR OTHER PERCEPTUAL FUNCTIONS AND CONCLUDING REMARKS

Having considered some of the implications of research on physiological stresses for other abnormal conditions, this final section will deal briefly with implications for other perceptual functions and with a few concluding remarks concerning further research. That severe physiological stresses such as anoxia and insulin hypoglycaemia and drugs such as alcohol and the barbiturates are likely to have a general depressant action on a wide range of functions is already clear from psychological and physiological research. What is not clear is precisely how and under what conditions other functions will be affected. Implications seem most obvious for anoxia and insulin hypoglycaemia for in both cases their effects can be described fairly satisfactorily in terms of the filter factor hypothesis. If this hypothesis is valid, it should be possible to make predictions about other perceptual functions which are known to be dependent on intensity of illumination.

Considering first other functions at what is traditionally regarded as the sensory level, anoxia and insulin hypoglycaemia might, for instance, be expected to cause changes in various spatial and temporal induction effects.¹ Limited data of McFarland,

Hurvich and Halperin (1943) suggest that the filter factor hypothesis may apply to the effects of anoxia on certain after-image phenomena. Following earlier research in which an inverse relationship¹ was found between the latency of the "tertiary" or Hess after-image and stimulus intensity, these authors found that the curve relating after-image latency to the intensity of retinal illumination was shifted along the horizontal (intensity) axis to higher intensities. The extent of this displacement appeared to be of the same order as in the case of the curves relating foveal visual acuity and brightness discrimination to illumination but their data are not sufficiently precise to decide whether the translation involves a slight vertical as well as an horizontal component. No experimental data are available on spatial induction but from electrophysiological and psychophysical data which suggest that simultaneous contrast is a function of intensity of illumination (Wilcox, 1932; Barlow, 1953) one would expect a reduction in contrast effects following anoxia at certain lower levels of illumination.

Extending the hypothesis to more complex functions traditionally considered under the heading of Visual Perception (more specifically, Visual Space Perception), displacements would be expected to occur in the curves relating thresholds for monocular movement parallax (Graham, Baker, Hecht and Lloyd,

¹ The influence of one part of the retina on another is described as *spatial induction*; by *temporal induction* is meant the effect of a primary stimulus on the response of the retina to a succeeding stimulus" (Dawson, *The Physiology of the Eye*, p. 88, 1950). Used in its broadest sense (Parsons, 1927) the term induction would cover the phenomena of adaptation and critical flicker frequency considered earlier in this chapter as aspects of discrimination.

¹ The general form of the function is curvilinear, latency decreases as intensity is increased, rapidly at first, then more gradually.

1948), and thresholds for stereoscopic vision (Mueller and Lloyd, 1948) to intensity. These few examples should be sufficient to give some idea of the possible scope of the hypothesis at different levels of visual functioning.

That the filter factor notion should apply to a number of different visual functions is not surprising when one considers that intensity of illumination is a fundamental stimulus variable in tasks making demands on visual discrimination. As the classical experiments on intensity discrimination, visual acuity and C.F.F. have shown, increasing the intensity of illumination has the effect of increasing the spatial and temporal discriminative ability of the visual system. Precise predictions about the extent of the effect for a given degree of oxygen deprivation and level of illumination could, of course, only be made in cases where the psychophysical functions themselves have been accurately defined over a wide range of stimulus intensities. This has been done for acuity, intensity discrimination and C.F.F., but only to a very limited extent for other aspects of perceptual discrimination. As Holway and Boring (1941) have so aptly remarked in another connexion, systematically determined functional relations are "wanted and wanting"; until they have been established, quantitative research on the effects of various abnormal conditions will be severely restricted in scope. From the limited data available one would expect many forms of visual discrimination to be greatly impaired under moderate degrees of anoxia at the lower levels of illumination whereas at the higher levels the effect would be negligible.

While the data reviewed in this chapter encourage application of the filter factor hypothesis to other visual functions it is already clear that changes in certain functions cannot be due solely to a reduction in the effective intensity of illumination. Thus, McFarland, Hurvich and Halperin (1943) found that administering oxygen for periods known to cause an increase in the apparent brightness of the visual field did not result in a recovery in after-image latency in subjects who had been exposed to low oxygen tensions. This suggested to them that other factors directly concerned with the velocity of the processes underlying the "eventuation" of the after-image are affected. Certain kinds of test-object used in experiments on acuity and anoxia have also revealed apparent discrepancies (Berger *et al.*, 1943) from a simple filter factor hypothesis.

These discrepancies, the apparent inability of the filter factor hypothesis to account for the effect of respiratory acidosis on C.F.F., the conflicting results of drug studies, the lack of well-established functional relationships in other areas of perception, and the paucity of knowledge concerning interrelations

between different sensory modalities make it premature to generalize very far beyond the rather narrowly-circumscribed area of visual discrimination. The immediate need is obviously for more extensive and, in certain cases (e.g. after-images and C.F.F.), more precise psychophysical data to specify the nature and extent of the effects of anoxia and other abnormal conditions. Having determined the psychophysical parameters which are affected, an attempt can then be made to determine the underlying physiological mechanisms.

Even when the psychophysical effect of different abnormal conditions appears to be the same, as in the case of the depressant action of anoxia, insulin hypoglycaemia, alcohol and the barbiturates, it cannot, of course, be assumed that the same physiological mechanisms are involved. Available data suggest that the mechanisms involved in anoxia and insulin hypoglycaemia may be similar. Both stresses are known to depress cerebral metabolism (Himwich, 1951) and the nature of the neurological changes as well as the order in which they occur, appear to be strikingly similar, but anoxia progresses on a much faster time-scale (Alexander and Himwich, 1939). In contrast to these stresses, the depressant action of alcohol on visual thresholds is probably mediated to only a very small extent by metabolic inhibition while the barbiturate group of drugs seems to exert its effect chiefly through direct interference with nervous activity by elevating the "synaptic threshold" and prolonging recovery time (Toman and Davis, 1949).¹ As Elliott, Page and Quastel have pointed out elsewhere, there is no reason to expect a common mode of action of central depressants "since there must be as many different ways of blocking central nervous activity as there are independent physiological parameters necessary for the normal maintenance of function in the central nervous system" (Elliott, Page and Quastel, 1955, pp. 516-517).

By integrating physiological research with psychophysical experimentation of a more analytic nature than has hitherto been carried out, it should be possible to obtain considerable insight into the finer mechanism of action of stresses and drugs, resolve some of the apparent discrepancies in the experimental data and provide information of great value to visual theory. Greater attention to the details of experimental conditions in dark adaptation studies and systematic variation of area/duration relationships of the test-field may, for instance, help to resolve some of the conflicting findings on drug effects and, at the same time, help to clarify the nature of the changes

¹ In view of recent research on centrifugal control of the sense organs (Granit, 1955), the barbiturates are a particularly interesting group of drugs owing to their marked effect on the reticular activating system (Goodman and Gilman, 1955).

in neural interaction which are supposed to occur during dark adaptation (Rushton, 1952). (Mandelbaum's (1941) entirely negative findings may have been partly dependent upon his particular choice of experimental conditions, in respect of stimulus size and duration (see page 141).)

The concluding remarks to this chapter must be essentially similar to those made earlier by Graham (1951) in his review of visual perception. The most pressing need in this field is for more experiments along the lines of those by Hecht, Wald, and McFarland and their associates, planned against a psychophysical and physiological background and designed to reveal functional relations. Only when more analytic data covering a wide range of values of relevant variables have been accumulated will it be possible to make really useful practical contributions to the solution of clinical problems or provide an adequate basis for the development of theory.

While it is perhaps too early to make pronouncements about the kind of theory which is most likely to advance our knowledge in this field, it would seem that to be useful a theory must make explicit the general relations implied in Graham's equation given on page 108. Theories of reception which deal with peripheral events and limiting conditions in the visual process provide an obvious starting point for further experimental and theoretical development but these and similar theories for other sensory modalities need to be supplemented by physiological and behaviour theories which can describe more central processes and conditions of the organism. Theories of the latter type and the experimental data which they describe will eventually provide a broader basis for sense organ theories by making explicit factors which are assumed to be secondary or constant in theoretical derivations for the receptor process. But for the present and probably for some time to come it seems that research will have to be guided by theories of the first type and, where these prove inadequate, by any relevant generalizations which have been formulated in psychophysics and sensory physiology for useful theories of the second type do not exist. Building upon the solid foundations laid by these two disciplines seems the surest way of advancing the psychophysiology of perceptual abnormalities toward scientific respectability and practical usefulness.

CHAPTER 5

Intellectual Abilities and Problem-solving Behaviour

W. D. FURNEAUX

THE INVESTIGATION OF "INTELLECT"

THE writer has for some years been concerned with the study of intellectual functions in humans, in particular with the examination of concepts such as those of *speed*, *power*, and *difficulty*, which in spite of the important role they must inevitably play in any theory of "intelligence," have been developed in a fashion so haphazard that even their definition is a matter for controversy. The results of these inquiries have circulated freely within the Institute of Psychiatry, but have not been widely reported elsewhere. The writers of some of the other sections of this HANDBOOK have thus found themselves in the difficult position of wishing to incorporate in their contributions a background of results and ideas with which their readers will not be familiar. The function of the present chapter is to sketch in this background, rather than to discuss in detail any aspect of abnormal function. It could well be regarded primarily as an introduction to the following chapter.

The study of the abnormal could proceed, in theory, in the absence of any clear understanding of normal mechanisms, but since these disparate fields must in the end be related in terms of concepts which are applicable to both, any change of outlook in the one will inevitably be reflected in the other. The point of view now to be described has been judged, by some, to be of value in connexion with the investigation of intellectual functions in patients demonstrating behaviour disorders, but it developed as a result of an attempt to investigate the normal determinants of score in so-called intelligence tests. The repeated demonstration that performance in "real-life" situations (e.g. success in examinations) can be predicted with reasonable accuracy from a knowledge of such scores provides ample justification for their use. The score given to a subject by such a test, however, describes his behaviour while taking it only very incompletely. This incompleteness does not arise because the score relates only to some *selected* aspect of the total behaviour, as do most scientific measure-

ments. It arises because it attempts to summarize the results of the interaction of several apparently complex processes. The possibility must therefore be considered that the empirically demonstrated relationship between test score and real-life performance really reflects an even closer relationship between such performance and some restricted part of the total test-solving activity, with the other determinants of test score serving only to introduce an unnecessary error variance. In order to minimize error variance an attempt must thus be made to maximize the number of categories into which the subject's total test-taking behaviour can be subdivided, and in terms of which it is to be scored. Obviously, types of response which are logically distinguishable might involve separate determinants, so that ideally, the process of dissection should continue until further subdivision within any category becomes impossible.

It thus appears that the only really satisfactory approach to the study of test-taking behaviour is that of the thorough-going logical-atomist. This approach does not involve the rejection of the important theoretical and experimental contributions to the study of cognition which have been made by proponents of the various kinds of field theory (among whom, for the purposes of this discussion, must be included Piaget), but rather a refusal to recognize that there is any essential antithesis involved in the two kinds of formulation, except in so far as field theorists tend also to stress the importance of the concept of emergence. Any field can be specified in terms of the interaction of a set of discrete determinants, to just the same extent as can the output of a binary computer, and field theories *per se* do no more than direct attention to a particular type of possible interaction among determinants.

If the determinant A is associated with behaviours a_1, a_2, \dots, a_r , etc., and determinant B with b_1, b_2, \dots, b_r , etc., then according to the doctrine of emergence the interaction of A and B may lead to

behaviours of the order (a, b, Δ) and not (a, b) , where Δ is some component which cannot be predicted from a knowledge of A and B . This being the case, behaviours (a, b, Δ) can be predicted by tests involving A and B in interaction, but not by the manipulation of scores derived from separate tests of A and B .

In a situation where one has the determinants and is examining the results of their interactions the concept of emergence may have its uses. Where the behaviour is known and its determinants are sought, however, the concept seems to border on the metaphysical. If tests A and B , between them, predict only a part of the variance associated with a behaviour, it is difficult to imagine any experiment which would show that the remaining part depended on interaction effects between determinants A and B rather than on the effects of, say, C . The relevance of any particular C could always be subjected to scrutiny, but not that of all possible C s. It is quite certain, however, that any attempt to pursue the problem at all would require the existence of measures for the individual determinants A, B, C, D, \dots , etc., rather than mixtures of several of them in unknown proportions.

The concept of emergence, in so far as it is not simply an acknowledgement of ignorance, does no more than re-state the fact that the relationships with which science is concerned are descriptive, and not explanatory. If the interaction of A and B leads to events of an order (A, B, Δ) rather than (A, B) all that matters is to discover whether a specific interaction leads repeatedly to a particular event (E) or not. If it does not, even to a useful degree of approximation, then the phenomena concerned cannot be made the subject of any kind of scientific study. If it does, then the successful prediction that E will occur would seem to depend entirely on our ability to distinguish A, B, E , and the interaction concerned, from the general background of other irrelevant phenomena, i.e. successful prediction presupposes adequate atomization.

The development of cognitive tests does not seem to have been guided, to any great extent, by considerations of the type which have now been advanced. Thorndike (1926) was clearly aware of, and critical of, this defect. He asserted that tests of intellect displayed "ambiguity of content, arbitrariness of units, and ambiguity of significance," and suggested that at least three scores, rather than one, were needed to describe intellectual ability. The first of these was to be a measure of the range of operations a particular intelligence could perform, the second was concerned with the rate at which these operations could proceed, and the third with the maximum level of difficulty at which satisfactory operation could be achieved. The present writer's whole approach to the measurement of human intellectual function has developed out of

ideas which found their earliest systematic presentation in this volume. Thorndike's development of them seems to have been hampered, however, by an approach that was at times over semantic, and by a failure to define his fundamental concepts with sufficient rigour. He was particularly concerned with an attempt to define an entity called "the intellect" (Thorndike, *The Measurement of Intelligence*, 1926; cf. the long discussion on p. 25 *et seq.*), rather than to develop the atomistic framework of description which would seem to have been the logical result of his own insights.

Spearman himself attempted to define three different components of intellect, but there seems to have grown up, among British psychologists at least, a very strong tendency to use "g" as an explanatory concept not itself amenable to further subdivision. The preconceptions of the majority of workers are well demonstrated by the titles under which they have reported their results, the archetype involving some such formulation as: "An attempt to find a factor of 'speed' as opposed to 'g.'" The danger of such preconceptions is well illustrated in a paper by Sutherland (1934), who examined the intercorrelations between three measures of the time taken to solve simple problems correctly, and one measure of g. He argued that, since score in the g test was not a speed measure, the existence of a factor of "speed" within the three time tests could only be assumed if their intercorrelations remained significant when the contribution of g was partialled out. As their average residual correlation with g eliminated was only about 0.12 he concluded that no speed factor existed. He does not appear to have noticed that the average correlation between time scores and g scores was about 0.57, while the average of the reliabilities of the time scores was about 0.57 also. The greater part of the non-chance variance of each of the time scores must thus have been determined by g. If, therefore, g is assumed to be independent of speed the ludicrous conclusion must be accepted that the time taken to solve problems is not a measure of speed.

It is, of course, possible, although rather unlikely, that the perfect g test is concerned only with the effects of some single determinant. It seems much more probable, however, that cognitive tests display positive intercorrelations because rather similar interactions of the same set of determinants play an important part in determining score in all of them, and the foundations of an adequate knowledge of the nature of test-taking behaviour must be based on the study of these individual determinants and of their modes of interaction.

It seems to the writer that the application of the statistical technique of factor analysis to large batteries of psychological tests (e.g. Holzinger,

1934-5 and Thurstone, 1939) with the object of defining group-factors in terms of which intellectual function can be described, has done less to advance our knowledge of intellectual mechanisms than is commonly assumed. It is difficult to resist the conclusion that all this work has been rather too empirical, and that most of it will eventually have to be repeated. It is often very useful to know how particular test-scores relate together, but if, as seems probable, most test-scores reflect the interaction of a set of attributes whose composition and relative importance are a function both of the exact details of construction of the test (e.g. the range of difficulty covered by the items it embodies) and also of the characteristics of the group within which it is used, then generalization from the findings of a particular investigation becomes almost impossible. It is not without significance that, after three decades during which test-scores of the conventional kind have been the basic data upon which factorial studies have been erected, nothing even remotely resembling an acceptable theory of cognition has been evolved. This is not the fault of the technique of factor analysis, which has in fact the unusual power of serving at the same time as a means of analysis and also of synthesis. It could perhaps be claimed that the factor-analysts have, on the whole, given very adequate answers to questions which have not always been very carefully formulated.

Within even the most carefully designed of existing "single-factor" tests analysis will reveal the existence of logically distinguishable categories of response whose possible effects on score demand separate consideration. Thorndike's subdivisions of "speed" and "altitude," for example, together with related concepts such as "accuracy," seem to be applicable to most of them. It follows that it is impossible to know just what significance can legitimately be assigned to these "factors." Vernon (1950), for example, has suggested that the "w" and "f" (fluency) factors of the Primary Mental Abilities studies are differentiated from the verbal factor "v" only in terms of the level of difficulty at which the two kinds of score were obtained. The following brief analysis will perhaps serve to direct attention to a further ambiguity of a similar kind.

Suppose that there are two relatively independent attributes, say "speed" and "accuracy," each of which affects test performance separately in a way which varies with the difficulty of the test and with the time allowed for completion, but not with test content. In any heterogeneous set, tests will vary in difficulty and in the time allowed for completion, and the correlations between tests could therefore reflect these differences as well as, or even rather than, those associated with content. In view of this possibility each of the fifty-seven tests used in the original P.M.A.

experiment was considered in turn, and a decision made as to whether it was likely to have served as a measure for speed or for accuracy in the experimental population used. In making this decision consideration was given to any experience the writer might have had in using the same, or a similar test within a British population of university students, to the method of scoring adopted, to the shape of the distribution of scores, to the time allowed, and to the apparent difficulty of the test items as gauged from a brief scrutiny. In respect of thirteen tests no decision could be made with even moderate confidence. Sixteen seemed to be concerned mainly with speed, ten with accuracy, and eighteen with both. In order to simplify the analysis the factors isolated from Thurstone's matrix by Eysenck (1939), using Burt's group-factor method, were used instead of the oblique solution favoured by Thurstone himself. In Eysenck's study only four factors were of any great importance, the remaining five each accounting for less than 2 per cent of the total variance. One of the four factors concerned was a general factor accounting for some 31 per cent of the total variance, the others being Verbal-Literary (5 per cent), Arithmetical (4.6 per cent), and Visuo-Spatial (6.6 per cent).

After the speed/accuracy dependence of all fifty-seven tests had been estimated the nine tests having loadings greater than 0.3 on the Arithmetical axis were examined. Six of them had been designated measures of speed, one of accuracy, one mixed, and one unclassified. Of the fifteen tests defining the Visuo-Spatial factor, five had been designated measures of accuracy, seven mixed, two speed and one unclassified. Both speed and accuracy are represented to an approximately equal degree within the Verbal-Literary tests, four being measures of speed, three mixed, and two accuracy. Of the seventeen tests having loadings above 0.65 on the General-Factor only one represents speed, while no less than six had been designated accuracy. At g saturations below 0.4, on the other hand, four of the nine classifiable tests measured speed, and only one accuracy.

It would be absurd to make too much of so cursory an examination. The evidence could, however, be interpreted as supporting the hypothesis that at least part of the apparent differentiation between Visuo-Spatial and Arithmetical tests is not due to differences of content at all, but to differences in the extent to which they measure speed as opposed to accuracy. The association of tests measuring accuracy with high loadings on the General-Factor is of interest in that it helps with the interpretation of the Factor. It is not however really relevant to the point under discussion, and in the present context the analysis will have served its purpose if it illustrates the difficulties which attend the use of the kind of complex test that still

represents the psychologist's chief measuring instrument. It is rather as if the electrician had no means of measuring current and voltage independently, but could only use a wattmeter, to measure their product; or as if a tailor had to fit his customers from a knowledge of their weights.

In spite of its greater sophistication and range the monumental work of Guilford and his school, which is still proceeding, is of the same general kind as were the earlier studies (*see* Guilford, 1956, for a good summary of this work). The scores upon which the analyses are erected must all be based upon such complex interactions of material, operation, and context, that the disentangling of the true basic determinants, even with the aid of the most refined of correlational techniques, must be virtually impossible.

There has been an uneasy awareness of the unsatisfactory nature of psychological-test scores for several decades. It has been reflected in the work of Thorndike, and of the Factorists, but the approach of those who have participated in the speed-power controversy, although often extremely confused and unsatisfactory, seems to the writer to have displayed the most accurate assessment of the real nature of the problem. The search for a speed factor within intelligent behaviour began even before the first intelligence tests came into existence (e.g. J. Cattell's experiments at Columbia in 1894). Many workers, on the other hand, have denied the need for the separate measurement of speed, pointing to the high correlations between scores in timed and untimed tests in support of their contention. A paper by Sutherland was mentioned rather critically on a previous page (Sutherland, 1934), but its defects lay only in the initial acceptance of an unjustified assumption, in every other respect it displayed a standard of competence which could well have been taken as a model by the majority of participants in the controversy. Most studies have suffered from an astonishing degree of technical inadequacy. Speed was usually assessed by giving what was in part an accuracy score, such as the number of items solved correctly within a time-limit test. Alternatively, it was defined in terms of the total time required by the subject to complete a test, with complete disregard of the fact that correct and incorrect responses, as well as abandonments and omissions were thus assumed to be equivalent. Terms such as *power* and *level* seem sometimes to have been regarded as interchangeable, but at other times to involve important distinctions, while either might imply the total score under time-limit conditions, or alternatively under untimed conditions, at the whim of the author. Scores of these unsatisfactory types were then intercorrelated and the resulting coefficients interpreted with complete disregard of the part/whole

effects which they almost invariably incorporated. It is hardly surprising that the question as to whether speed of response demands separate consideration as a determinant of intelligent behaviour is still regarded by some as being an open one. The relevant literature cannot be reviewed here—it is far too voluminous—but two important studies are worthy of note. Slater (1938) has shown that within groups having a very small variance for score on a standardized intelligence test a very wide range of mental speeds (as measured by response-time per item correctly solved) can be demonstrated, and that these between-person differences in speed are associated with differences in school attainment. Tate (1950) has provided an able discussion of the problem of speed measurement, and has shown experimentally that such measurement can be accomplished with a very high degree of reliability and validity. Furneaux (1948) has also reported work which both supports and supplements that of Tate. Taken together these contributions suggest most strongly that the simple, unambiguous scores which result from properly considered measurements of response-rate are theoretically sound and also useful in practice. It occurred to the writer that they also have the merit of being scores of a kind which cannot easily be redefined in terms of sets of simpler determinants, and that they therefore satisfy the requirements elaborated in the opening paragraphs of this chapter. The question seemed to arise, therefore, as to whether it might not be possible and profitable to consider the human problem-solver (and thus the cognitive-test-taker) simply as a "black-box" whose input-output characteristics require to be specified in terms of unambiguously defined observations. This involves the setting on one side of the whole of the approach to cognitive function which originated with Binet and has come to be taken for granted ever since. Instead, we must approach problem-solving as if it were some kind of multiple-choice reaction, to be dealt with as far as possible by an extension of the classical stimulus-response approach which characterized the earliest days of systematized psychological research, and which was shown to be of value by such workers as Kirkpatrick (1900) and Kelly (1903). It is perhaps arguable that, if the orderly progress exemplified by such experiments had not been virtually halted following the publication of Binet's work in 1905, the whole field of psychometrics might by now have been far more soundly based than it is. This is not of course to argue that one should attempt to ignore the immensely valuable results which have been obtained by Binet and the mental-test movement which he founded. Binet's accomplishment in this field, however, was to devise a brilliant solution for an urgent practical problem, the solution involving the design of a novel form of school examination.

Psychologists have been feeling their cautious way back from this toward a genuinely scientific system of measurement ever since.

The relevance of the discussion, so far, to the study of abnormal (or normal) intellectual function can perhaps be illustrated by an example. At the present time one question frequently asked about the effects of psychoticism on intellectual function is something like: "Is the intelligence of psychotics reduced as compared with that of normals?" A very large number of studies has been made in an attempt to answer this question, with conflicting results. A typical experiment involves the administration of a standardized intelligence test to a sample of schizophrenics and to a sample of normals, followed by a comparison of the scores achieved by the two groups. The score a person achieves in a conventional intelligence test is a simple function of the number of problems which he can solve correctly, from a set which are given to him, in a particular specified time. His final score thus depends in part on how long he has to spend in obtaining those answers which prove to be right, in part on the amount of time he wastes in evolving answers which prove to be wrong, and in part on his ratio of right to wrong answers.¹ Unless these three determinants of score are highly correlated within both normal and schizophrenic groups it is impossible either to interpret the results of the experiment satisfactorily, or to generalize from them. If normals and schizophrenics achieve much the same scores, this may indicate that the problem-solving characteristics of both groups are virtually the same. The same result could arise, however, if schizophrenics were less accurate than normals but obtained both right and wrong answers more quickly. Alternatively they might be equally accurate, but might be quicker at arriving at incorrect solutions and slower at reaching correct ones. If this latter explanation were correct, then it would follow that if the experiment were repeated using an intelligence test in which the average difficulty of the problems was increased, then a different result would be obtained in that the schizophrenics would obtain higher scores than the normals. Even where the equality of scores arises from an identity of problem-solving performance between the two groups, it could not be assumed that a similar identity would arise in connexion with an easier or more difficult test, since this would be to assume that comparisons of performance made at one level of difficulty would be valid for problems at other levels. The methods of item analysis used in the construction of intelligence tests ensure that comparisons of accuracy made at one level of difficulty within normal groups bear some relation to those which

would be made at another,¹ but they take no account of rate at all, and the item analyses made within normal groups are never repeated within the abnormal groups for which the tests are nevertheless assumed to be valid.

This list of shortcomings is far from exhaustive, but it will probably suffice to show that little useful information about intellectual functions can be obtained from the use of conventional intelligence tests in the absence of an adequate theoretical and experimental analysis of the ways in which a person's responses, first to single problems and then to carefully defined sets of problems, can legitimately be scored. An attempt will now be made to sketch in the bare skeleton of such an analysis and to report briefly on the results of some experimental work to which it has led, and to discuss some of the implications of both theory and experiment.

The Analysis of a Formalized Problem-solver

Scientific investigation has always to start with the brutal oversimplification of the phenomena with which it is concerned. In order to lay the foundations of the study of problem-solving behaviour it is necessary to ignore many attributes which undoubtedly influence problem-solving responses, and to concentrate at first on a few limited fields of study. It facilitates such an approach if we formalize the human problem-solver, regarding him simply as a problem-solving-box (*PB*) having only such characteristics as we may explicitly assign to it.

Let *PB* be a problem-box containing an unspecified mechanism, of such a nature that when it is supplied with an input *I* in the form of a problem, an output is produced which represents an attempt to solve the problem. Suppose that each such output is designated an *essay*,² and is represented by the symbol O_r .

This input/output relationship can conveniently be set out in symbolic form, i.e.—

$$I[PB] \rightarrow O_r$$

Suppose that a time, t_r elapses between the feeding in of the input and the production of the output. We can incorporate this additional information thus—

$$I[PB] \rightarrow O_r, t_r$$

After it has been produced any O_r can be inspected and a decision made as to whether it is right or wrong. Let any O_r which represents a right answer be reclassified as O_r , while O_w stands for a wrong answer, and let t_r and t_w be the values of t_r relevant

¹ As will appear, even this statement is not strictly true.

² The term *essay* has been used, because, although archaic, it leads to the use of *e* in suffix positions rather than other letters of a more ambiguous connotation. Thus the use of *trial* would involve the suffix *t*, which is already widely used in connexion with measurements of time.

¹ This analysis is not really adequate, as will appear, but will serve for the present illustration.

to O_r and O_w respectively. Thus all O_r and all O_w are also O_e , and all t_r and all t_w are also t_e .

Suppose now that it is observed that the repeated application of a particular input ${}_pI$ to a particular Problem-box ${}_xPB$ is followed by O_r on the proportion of occasions q_r , but by O_w on the remaining proportion, q_w , the sequence of responses being unpredictable save in cases where q_r has the value zero or unity. We can designate this symbolically thus—

$$\{{}_pI\}[_xPB] \rightarrow \{O_r\}^p + \{O_w\}^q$$

where the curly bracket has in each case the usual connotation of "a set of." Suppose further that even if attention is confined to $\{O_r\}$ the associated values of t_r are not all equal but vary in unpredictable sequence between the limits R_t and $(R_t + H_{tr})$, defining a distribution having a mean of \bar{t}_r and variance V_{tr} . Similarly let the $\{t_w\}$ associated with $\{O_w\}$ define a distribution having the limits W_t and $(W_t + H_{tw})$, variance V_{tw} , and mean \bar{t}_w . Then we can write—

$$\{{}_pI\}[_xPB] \rightarrow \{O_r\}^p, \{t_r\} + \{O_w\}^q, \{t_w\}$$

In order that the terms on the right-hand side of this relationship can unambiguously be associated with the results of applying a particular ${}_pI$ to a particular ${}_xPB$, even when set down in the absence of the left-hand side, it is convenient to add appropriate suffixes, thus—

$$\{{}_pI\}[_xPB] \rightarrow \{{}_{px}O_r\}^p, \{{}_{px}t_r\} + \{{}_{px}O_w\}^q, \{{}_{px}t_w\}$$

while the addition of similar suffixes to the distribution statistics, e.g. ${}_{px}V_{tr}$, shows to which problem and to which PB they relate. It will be convenient to use the symbol M to stand for the whole set of parameters of a particular kind, or for a particular distribution. Thus we have—

$$\begin{aligned} {}_{px}M_{tr} &\text{ comprises } {}_{px}\bar{t}_r, {}_{px}V_{tr}, {}_{px}R_t, \text{ and } {}_{px}(R_t + H_{tr}) \\ {}_{px}M_{tw} &\text{ comprises } {}_{px}\bar{t}_w, \text{ etc., etc.,} \end{aligned}$$

while

$${}_{px}M_{qr} \text{ comprises only } q_r.$$

Since both O_r and O_w are special cases of O_e it follows that we also have ${}_{px}M_{te}$, where

$${}_{px}M_{te} = {}_{px}M_{tr} + {}_{px}M_{tw}.$$

It is not necessary to give separate consideration to ${}_{px}M_{qw}$ since $q_w = 1.0 - q_r$.

Our assessment of the problem-solving characteristics of ${}_xPB$ must start with the collecting of sets of observations from which the values of these various "M-statistics" can be computed, all with reference to the inputs provided by a particular problem p . We can then collect similar data using the same input ${}_pI$

to other problem-boxes, ${}_yPB$, ${}_zPB$, etc., and in this way compare their characteristics in respect of this one problem. Although, for a particular purpose, interest may centre on a particular statistic, say \bar{t}_r , we must not make the mistake of assuming that one statistic is of greater intrinsic importance than another, or of attempting to define the behaviour of a PB in terms of one statistic only in the absence of clear evidence that all are highly correlated. Nor must we compare, say, the value of \bar{t}_r derived from one PB with the value of \bar{t}_w or q_r derived from another, and imagine that the comparison has a meaning. It would be equally unwise to set up a score which was a more or less undefined function of a lumping together of several of the statistics and then to imagine that it could have more than an accidental significance. All these strange operations are involved in current mental-testing procedures, although often to a rather mild degree.

The value of any measurement of behaviour can be assessed only in terms of the extent to which it relates to other measurements of different kinds (for the purpose of theory construction) and to various kinds of "real-life performance." There is no *a priori* reason why the sets of M -statistics associated with each of a properly selected set of single problems should not turn out to represent a set of scores which have a greater value, thus assessed, than scores derived from tests made up of assemblages of problems.¹ In order to pick out the most useful set of single problems from among all possible problems it is necessary to find ways in which problems can be classified, and it is at this stage that concepts need to be introduced similar to those of "difficulty" and "type" which are in current use.

The concept of difficulty arose originally because, on introspection, the sense of effort associated with attempts to solve some problems is stronger than that associated with others. By analogy with the fact that, for example, differences in experienced brightness intensities can be related to a measurable property of the relevant stimuli, an attempt was made to relate differences in experienced effort to a measurable property of problems—their "difficulty." Unfortunately, on inspecting problems, no such property can be observed, nor can it unambiguously be associated with any of those properties of problems which can be observed such as the number of symbols which are required for their presentation. In spite of this the idea that a problem "has" a difficulty, the value of which can be discovered by suitable measurement, has persisted, and the procedure commonly employed

¹ Once the discussion moves from the consideration of PBs to that of actual human subjects it becomes necessary to reconsider the validity of this statement, because of complications arising from the effects of practice, etc., when a single problem is solved repeatedly.

in order to discover the difficulties of problems is to scale them in terms of the number of individuals in some defined group who fail in their attempts to achieve an acceptable solution. Recognizing that the "difficulty-values" thus allotted are a function of the group within which the calibration has been made, the more sophisticated approaches involve attempts to transform the values thus obtained into the values which would have been observed in some such group as "an unselected normal population," or even to define a scale having an absolute zero (Thorndike, 1926). Controversies have arisen from time to time as to whether the measurement of difficulty is most accurately carried out in terms of observations of the number of people who fail a problem, or of the time taken for satisfactory solutions to be achieved.

The notions underlying this approach may be well founded, and the development of information-theory concepts may eventually make it possible to scale problems for difficulty in terms of the right kind of analysis of their structure. So far, however, they seem to have led only to confusion. It seems better to accept the fact that problems can only be classified in terms of the differences in response characteristics which they evoke. We can justifiably scale them in terms of the values of \bar{t}_i , V_{ti} , q_i , etc., which are associated with them, but no useful purpose seems to be served by the choice of one particular statistic as being a measure of "difficulty," or by discussion as to which statistic affords the best measure of "difficulty." It is necessary to bear in mind, moreover, that any scale is intended to fulfil a particular limited classificatory function, and scales evolved in connexion with the responses evoked by problems must be constructed with this function in mind. Since all the components of response which have so far been discussed would seem to have much the same *a priori* importance, and since, in the absence of experimentation, their interrelationships are not known, it is necessary, in the first instance, to define a separate scale in connexion with each component, i.e. for our present purposes, in connexion with each of the M -statistics. It is convenient to call such scales " D -scales." That scale which is concerned with the ordering of problems in terms of the values of \bar{t}_i , which they evoke can usefully be designated the $D_{\bar{t}}$ scale, and in terms of the same convention the D_{V_t} scale will relate to values of V_{ti} , D_{q_i} to values of q_i , and so on.

To consider the $D_{\bar{t}}$ scale as an example, the problem of scale construction is to assign to every problem a $D_{\bar{t}}$ scale position such that if any $_{px}\bar{t}_i$ is measured then for any other input set $\{_{qx}I\}$ the relevant value of $_{\alpha\alpha}\bar{t}_i$ can accurately be forecast from a knowledge of $_{px}\bar{t}_r$, the scale position of p , and the scale position of q . If the scale position allotted to q is denoted by

$_{q}D_{tr}$, then the requirement can be stated symbolically, and in a slightly modified form, thus—

$$\begin{aligned} _{q}\bar{t}_i &= f(_{q}D_{tr}, _{\alpha}K_{tr}) \\ &= f(D, K)_{tr} \end{aligned} \quad (1)$$

where $_{\alpha}K_{tr}$ is an individual constant assigned to $_{\alpha}PB$ in terms of the value of $_{px}\bar{t}_r$ which is observed for it. The crucial requirement, of course, is that the form of $f(D, K)_{tr}$ must be the same for all individuals, only the value of K_{tr} differing from one person to another. Once the double task is completed of finding a form for $f(D, K)_{tr}$ and scale positions for p, q , etc., such that equation (1) is satisfied, all comparisons between individual PB 's in terms of \bar{t}_i can be made in terms of one measure per PB (i.e. K_{ti}) instead of in terms of all the values of \bar{t}_i relevant to all possible problems.

Correlational studies using conventional test-scores have shown that performance in one kind of test cannot necessarily be forecast from a knowledge of performance in another kind. Such results suggest rather strongly that it may not be possible to arrange all possible problems along a single D_{tr} scale for use in conjunction with a particular form for $f(D, K)_{tr}$. We must be prepared to find that problems fall into sets (which may or may not involve differences of content analogous to the r, s, f, r , and other factors which result from the factor analysis of conventional test scores) for each of which a different D_{tr} scale and a different form for $f(D, K)_{tr}$ may be required. The members of any one set of problems may be said to define a particular *type* of problem. In the absence of experimentation it is impossible to say whether attempts at scale formation will lead to the discovery of a relatively small number of clearly discrete types, or to that of an infinite number which shade imperceptibly one into the other. In face of the latter eventuality it would be possible to define discrete types, for practical purposes, by assigning to the same type all those problems whose \bar{t}_i values could be specified in terms of the same D_{tr} scale and the same form for $f(D, K)_{tr}$, within the limits of some specified degree of error. It is also possible that all attempts to construct D_{tr} scales, applicable without alteration to all PB s, might fail, but that subgroups of PB s could be defined within each of which all the members could be covered by a common scale. Although the construction of D scales can be carried out empirically and has a purely classificatory function it will be clear on reflection that the form of the function $f(D, K)$ which is relevant to a particular scale is contingent on the nature of the mechanism within PB whose functioning intervenes between the feeding in of an input and the appearance of an output. At this point the analysis thus has important implications in connexion with the study of abnormal behaviour. If it is

found that the form of $f(D, K)$ relevant to a particular D scale is different in an abnormal group from that found for normal groups then it can be inferred that the actual nature of the problem-solving mechanism differs between normals and abnormals. If the $f(D, K)$ is common to both groups, however, then the nature of the mechanism is probably the same, although normals and abnormals might still be differentiated in terms of some of the K s relevant to the M -statistics. So far as the writer knows there have as yet been no investigations of this kind.

The argument which has been conducted in terms of the D_{ir} scale is equally applicable to all the other scales implied by the statistics comprised within M_{ir} , M_{te} , and M_{qr} . The primary concern of the psychometrician should thus be the construction of D scales, and in the absence of such scales there is no really satisfactory basis for the economical comparison of the problem-solving characteristics of different PB 's or classes of PB . Given such scales, with each of which will be associated a particular $f(D, K)$, all comparisons will be made in terms of the K values relevant to the M -statistics associated with the types of problem which are being subject to study. Values of K can either be measured by the application of a particular $\{_{px}I\}$ or by computations based on the form of $f(D, K)$, following the single application of each of a number of problems which are members of the same D scale, and whose D positions are known.¹ Every kind of K value has an unambiguous meaning, however derived, in that it specifies the numerical value which would be observed for a particular M -statistic if a particular standard problem were applied to a particular PB . Questions of standardization, etc., do not therefore arise, although they are replaced, of course, by the problems involved in setting up D scales. As will appear, these latter are much more susceptible of solution than are those of defining, and collecting, a stratified sample from which can be deduced the characteristics of "an unselected normal population."

It is now necessary to modify the definition of a PB in order to take account of a property of the human problem-solver which has an important effect on his characteristics, although it seems never to be taken into account. When attempting a set of problems, as in a test, the subject is not willing to spend unlimited time on any one item. Faced with a difficulty which cannot be resolved within what, under all the circumstances seems to be a reasonable time, the reaction is to abandon the problem concerned, and to pass on to the next one. The length of time for which the subject continues to work at a particular problem has as one of its determinants his persistence, but this is

not the only factor involved, since the decision to abandon an item may sometimes be made on grounds which involve an intelligent assessment of the effects on score of attempting a lot of items rather than persisting with a few. It will be convenient, therefore, to designate the attribute as "Continuance," or C , a term free from any aetiological presuppositions. PB may be given characteristics analogous with those resulting from C by adding to it a device ST having the functions of a time-switch.

Let any input to PB be represented simultaneously at the input to ST . Let the normal state of ST be "off," but let it change to "on" immediately an input is received, and let it then remain in that state for a time t_s before reverting automatically to "off," at which time we can say that "Continuance has been exhausted." In the present context it is possible to consider only the simplest characteristics for ST , i.e. that it has no means of distinguishing between different problems as inputs, and that t_s varies between the limits S_t and $(S_t + H_{ts})$, defining a distribution M_{ts} of variance V_{ts} and mean \bar{t}_s , within which the sequence of t_s values cannot be predicted.

Let ST be coupled to PB , defining the composite device ($PB + ST$), or PS . Let the ST relevant to $_{\alpha}PB$ be denoted $_{\alpha}ST$ and let the PS which results when they are coupled be $_{\alpha}PS$. Let the coupling be of such a nature that PB cannot start its problem-solving activity until ST is "on," and that the problem-solving process within PB is terminated as soon as it reverts to "off." Let such termination be signified by the appearance of an output O_s from PB , different in nature from the O_c which marks the production of an essay, and analogous to the entering of a dash or a question mark in the answer space on the part of a subject. If PB produces an O_c before C is exhausted, then ST moves to "off" immediately, and without the occurrence of O_s . A value of t_s which would have been observed if ST had not been coupled to PB is thus deleted from the M_{ts} distribution, whose characteristics are thus altered. In order that we can refer unambiguously and economically to the distributions which would have arisen in the absence of coupling and to those that are actually observed from the coupled device it will be useful to denote the former by M_{ts} as previously and the latter by $M_{ts'}$. In a similar way, if C is exhausted before the value of t_c relevant to a particular input has elapsed, then an O_s will arise instead of the O_c which would have been observed in the absence of coupling, and a value of t_c will be lost from M_{te} . Let the resulting modified distribution be denoted by $M_{te'}$. Any statistic relevant to any M can be distinguished from that relevant to the corresponding M in a similar way, e.g. by V_{te} instead of $V_{te'}$. It will also be convenient to use the term "search" to denote the activity which is initiated

¹ Because of the effects of memory, this latter is the only feasible procedure with human subjects.

within PB by an input I , and which terminates with the production of an O_e , or when ST moves to "off."

It is now possible to show that the evolution of D scales and the practical measurement of the various M statistics is considerably complicated by the effects of C . Unless these complications are taken into account, any attempt to compare normal and abnormal individuals, whether by using conventional tests or otherwise, may give rise to very misleading

never be switched off by the intervention of αST , but always following the appearance of an O_e . In this region of D all M_{te} statistics are therefore unaffected. At D values greater than Z the αPB will always be switched off by αST before an O_e can appear. In the region X to Y the number of O_e appearing after the lapse of times having values lying near to line B will be reduced, because on a proportion of occasions the αPB will be shut off by αST before they have time to

FIG. 5.1. THE INTERACTION OF SPEED AND CONTINUANCE, THEORETICAL

results. Terminological and other complications of considerable complexity result unless, in analysing the effects of C , the simplifying assumption is made that all types of D scale are identical. In the discussion which follows, therefore, the general term D scale will be used to cover all the scales D_{tr} , D_{tw} , D_{ol} , etc., unless the contrary is stated. Once the analysis has been completed in these terms the validity of the assumption can be tested experimentally.

Consider the relationships shown in Fig. 5.1 where the lines A and B , originating at t_a and t_b are supposed to define, for αPB , the longest and shortest times required for the production of an O_e at any value of D , there being no coupling between αPB and αST . The lines D and C define the longest and shortest values of t_s which relate to the uncoupled αST , these values, $(S_t + H_{ts})$ and S_t , being the same at all values of D . If αST and αPB are now coupled, the characteristics of the coupled device, PS , can be deduced from the diagram. At values of D less than X the αPB will

appear. All those O_e appearing after times lying near to line A will however still arise. Between Y and Z the αPB will always have been switched off before any O_e having $t_e > (S_t + H_{ts})$ can arise, so that for that small number of O_e that can emerge at all, values of t_e in the region of line A will predominate strongly. For D values greater than X , therefore, M_{te} will differ from M_{tr} at all values of D , the difference becoming extreme at D values which approach Z .

It is important to realize that the actual values of D which correspond to the points X and Z will differ from one PS to another, depending in part on K_{tr} and in part on \bar{t}_e . It will be useful to refer to problems having D values in the range $D = X$ to $D = Z$, for a particular PS , as problems which, for it, constitute *ambiguous-inputs*, or I_a . (Strictly speaking, of course it is not the inputs which are ambiguous, but the statistics based on their outputs.) The term I_u (unambiguous-input) will have the obvious complementary meaning. It will also be useful to use the

term *critical-D-value* for values of D , such as those which have so far been denoted by X and Z , at which there is a transition from I_a to I_u , or vice versa. The critical value for the M_e statistics can be denoted by ${}_cD_{te}$, and that for M_s by ${}_cD_{ts}$.

If the characteristics of ${}_aST$ be considered, then for $D > {}_cD_{ts}$ all the M_{ts} statistics are identical with those of M_{ts} , for no O_e arise. For $D < {}_cD_{ts}$, on those occasions when the uncoupled t_s approaches the value $(S_t + H_{ts})$ an O_e is more likely to intervene before switch-off occurs than is the case when it approaches the value S_t . In this region, therefore, M_{ts} will differ from M_{ts} at all values of D .

Given only the M statistics (relevant to the region where D has a value greater than ${}_cD_{te}$ but less than ${}_cD_{ts}$) there is no way of deducing from them the M statistics, and thus no way in which data can be obtained relevant to the problem of defining a form for, say, $f(D, K)_{tr}$, which is applicable to all PS . Any comparison between PS s which is made by using problems for which $D > {}_cD_{te}$ can apply only to the particular D value, or values, concerned. The statistics being compared, moreover, are not the carefully defined quantities \bar{t}_e , V_{te} , etc., but composite measures depending in unknown proportions on both the statistics of M_{te} and also of M_{ts} .

A human subject is always observed in his role as a PS , and can never be split up into the components PB and ST . There may well, therefore, be very considerable ranges of D values within which attempts to compare sets of subjects will be unsatisfactory in that the problems concerned will represent I_a for at least some members of at least some sets. For such a subject the statistics observed when problems are administered will be M rather than M , and will thus be useless. It follows that tests designed to measure M_{te} statistics within heterogeneous groups will probably have to consist of rather "easy" problems. The only alternative is to try to raise \bar{t}_e to such a high value that interaction of M_{te} and M_{ts} does not occur even at high D values. This would mean ensuring very high motivation for all individuals tested, and administering problems one at a time in a face to face situation so that problems were not abandoned as a result of a desire to attempt all those appearing on a test-sheet.

Fig. 5.1 has been used to illustrate the general case of O_e responses, but it could be applied equally well in connexion with the temporal characteristics of either O_r or O_w responses separately. Since the $f(D, K)$ relevant to D_{tr} and D_{tw} scales may differ, and since the M_{tr} statistics may have numerical values different from those for M_{tw} , it follows that an input which is I_u when it results in an O_r response might be I_a if it gave rise to an O_w . It is thus necessary to refer to inputs which are $I_{a(tr)}$ or $I_{a(tw)}$ to prevent ambiguity.

In the same way there will be one *critical-D-value*, ${}_cD_{tr}$, which is relevant to O_r responses, and another, ${}_cD_{tw}$, for O_w responses.

If O_r responses are now considered, then by analogy with the argument which has just been considered for O_e responses in general, a proportion of potential O_r responses will be lost when $I_{a(tr)}$ inputs are employed, being replaced by an equal number of O_e responses. Given a knowledge of the form of $f(D, K)_{tr}$ and of the statistics of M_{tr} and M_{ts} , it is possible to compute exactly what proportion of potential O_r responses can actually arise at any specified value of D_{tr} for a particular PS . This proportion will be unity at $D_{tr} = {}_cD_{tr}$, and zero at $D_{tr} = {}_cD_{ts}$, so that the complete curve relating the proportion of potential O_r responses arising (P_r) to the D_{tr} value of the input will have a form bearing some relationship to that shown by the curve B in Fig. 5.2. It will be convenient to call this curve the *completion-characteristic*. It should be noted that this characteristic cannot be computed, as might at first be thought, by making a direct count of the ratio of O_r to O_e responses at each value of D , since any particular O_e may represent an unrealized O_w rather than O_r .

To problems at any value of D there will be a relevant value of q_r . Let the relationship between q_r and D be something like that shown by the *accuracy-characteristic* represented by the curve A of Fig. 5.2.

The probability ($P_{r,q}$) that an O_r will actually be observed at any value of D is clearly the product of P_r and q_r . If K_{tr} has only a moderate correlation with K_{ts} and \bar{t}_e , then for different PS 's the two curves A and B can differ in their relative and actual positions to a very considerable degree. Suppose that one untimed test of a conventional type involves items in the range P of D values (Fig. 5.2), while another covers the range Q . The curves A and B in Fig. 5.2 relate to a PS of low accuracy but high completion, and for it the only determinant of success in both tests is accuracy, since at D values such that completion is less than 1.0 all the responses would in any case be O_w . Suppose, however, that accuracy had been greater. Then the accuracy curve A would move to the right, towards the completion-curve. Accuracy would still be the only determinant of success in test P , but both accuracy and completion would be active in Q . If curve B moved to the left, indicating poorer completion, then test P would become a composite measure for both attributes, while if accuracy were a little greater and completion a little less then both tests would involve both determinants, but in different proportions.

Since completion is a function of the interaction of "speed" (as measured by K_{tr}) and "continuance" (as measured by \bar{t}_e) curve B will move to the left if either speed or continuance is reduced. The same mental

test, if designed and scored in the conventional manner, will thus measure different combinations of speed, accuracy and continuance when applied to different PS s. Again, if a PS is fed with different tests, all of the same type, but all covering different ranges of D , then the score derived from each such test can relate to a different attribute or combination of attributes. It is an interesting corollary of this analysis that a test set without time-limit is not

these items are sufficiently "difficult" to lead to the production of some incorrect solutions by most members of the group, none are so difficult in relation to the range of mental speed existing within the group as to be given up as insoluble. If such a two-part test is set with time limit, the slowest members of the group will still be working on the N_e easy items when the time limit expires, and for them the determinants of success will be speed only. The moderately fast

FIG. 5.2. THE INTERACTION OF COMPLETION AND ACCURACY, THEORETICAL

necessarily, or usually, a "speed-free" test. In any test which includes problems having D values which, for a particular subject, are greater than ${}_c D_{tr}$, score is determined in part by the completion characteristic, which is itself, in part, a function of speed (K_{tr}).

Some Implications

It seems that these conclusions, based on the analysis of a PS , must be applied equally to the human subject. Consider, as a further illustration, a test made up of items having such low D values that no individual in the population being examined returns any incorrect solutions. As the items are "easy" they will all be solved quite quickly, so continuance will not be a determinant of success. Under these circumstances the only factor influencing score if the test is timed will be K_{tr} for each subject, i.e. problem-solving speed. (If the test is untimed the group will of course exhibit zero variance.) Suppose now that following a set of N_e such easy items subjects have to proceed immediately to a set of N_m at higher values of D . To simplify the argument let us specify that although

individuals will all complete the N_e items, but at varying rates, so when the test finishes they will have been working for different times on the N_m items of moderate difficulty. During the time any individual is working on section N_m the rate at which his score will increase will be a function in part of his speed, but also in part, of his tendency to produce incorrect solutions. For this group of moderately fast individuals the final score attained will thus be determined in a fairly complex fashion both by speed and also by the frequency with which errors are produced. The very fast members of the group will all finish the test, but will be distributed in terms of their error tendencies. If, finally, a further set of N_d items, all at very high values of D , are added to the test, then the final score of the fast members of the group, who reach these N_d items within the time allotted will now depend in part on continuance, for those who are less continuant will lose possible increments of score through abandoning their efforts to obtain a solution before a sufficient time had elapsed for a solution to have a reasonable chance of emerging.

Any test can be regarded as consisting of $N_e + N_m + N_d$ items. If such a test is administered with time limit to a fairly homogeneous group it could measure mainly speed, mainly accuracy, or mainly continuance, depending on the interaction of the range of ability represented in the group, the time allowed for the test, and the numerical values of N_e , N_m , and N_d . In a fairly heterogeneous group the attributes measured, under certain conditions, could vary all the way from pure speed, for some individuals, and through various combinations of speed, accuracy and continuance. If unlimited time is allowed the manner in which these combine to determine the final score will be modified, but the same types of complication will arise as when a limit is imposed. It would thus appear that such a test cannot be said to measure any single, clearly defined trait, and that under some circumstances the same test will be comparing different subjects in terms of quite unrelated attributes. Conventional tests are therefore not very suitable for use in connexion with the comparison of normal and abnormal individuals, since if differences are demonstrated they will be as much a function of the range of D covered by the test items as of the attributes of the subjects.

If the same test measures different qualities in different individuals, it also seems to follow that each separate application of the same test to the same individual will tap different qualities if the intellectual powers are still developing during the period throughout which the test is repeated. Thus the determinants of score will be speed, accuracy and continuance in the case of (say) a ten-year-old child confronted with what is for him a rather difficult test. During the ensuing four or five years it is not unreasonable to assume that the child becomes more persistent, more accurate, and develops greater speed; although it does not appear that any measurements have as yet been made of the mode of development of these separate qualities. Should such changes in fact take place, the result would be to reduce the contribution made by the effects of continuance and accuracy to the test score, so that eventually the most important determinant becomes speed alone. The selection of tests for longitudinal studies, relating to the constancy, or otherwise, of "intelligence" and of cognitive structure in general, must inevitably be greatly complicated by the need to take such possibilities into account. Whether successive measurements are made in terms of the same test material or not there would seem to be a high probability that the various determinations are in fact concerned with different interactions of the three basic traits. If this should in fact be the case it would go a long way toward explaining the results obtained by Anderson (1939) who found that the intercorrelations of successive "intelligence"

scores reported for children were actually somewhat lower than those that would be expected on the basis of part/whole effects alone even if each successive yearly increment of score was completely uncorrelated with the score obtained at the beginning of that year. There certainly seems to be every reason to believe that developmental studies have little meaning unless they are carried out in terms of properly selected M -statistics, and that this demands a careful choice of D values for the problems that are to be utilized.

Since persistence will usually be one of the determinants of continuance, and may under some circumstances become its major determinant, it would seem to follow that persistence must be one of the factors influencing scores in so-called cognitive tests which embody problems for which $D \gg_e D_{tr}$ for those attempting them. That such a correlation would be observed was predicted by the writer (Furneau, 1952, 1953) and subsequently confirmed by G. L. Mangan (Mangan, 1954) on the basis of a factor analysis of a battery which included both cognitive tests and measures of persistence.¹ Factor-analysing data reported by Bayley (Nelson, 1951), Hofstaetter (1954) too have suggested that persistence may affect cognitive test scores. In the writer's view no great weight can be given to Hofstaetter's findings, however, since as he himself is at pains to emphasize, the identification of the relevant factor as being one of persistence is based on a very tenuous argument. One would expect that in some forms of mental illness (such, perhaps, as the depressive psychoses) persistence might be greatly affected. The reduced cognitive-test scores sometimes reported as characterizing such illness might thus in reality be reflecting a change in an orectic attribute, as well as, or rather than, in a truly cognitive one.

The analysis also has other implications which are not directly relevant to the study of mental abnormality. For example, it would seem to follow that as the effective determinants of score are a function of the difficulty of the problems making up a test, then a factor analysis of inter-item correlations within a cognitive test should reveal one or more factors differentiating between items of different levels of difficulty. The emergence of such factors has in fact been reported from time to time (e.g. Guilford, 1941; Burt, 1942 and Vernon, 1950) and is clearly explicable in terms of the analysis here presented. It is only fair to add, however, that the cases so far reported might provide evidence for nothing of more significance than

¹ Readers of this chapter who also read Mangan's thesis may be puzzled to find that one or two of the arguments here presented also appear, word for word, in the thesis. Mangan was in fact quoting verbatim from material supplied to him by the present writer (Furneau, 1953). The relevant acknowledgement was, unfortunately, accidentally omitted from his typescript.

a statistical artefact (Ferguson, 1941; Wherry, 1944 and Gourlay, 1951), so that too much significance should not be attached to them. The analysis is also obviously relevant to the theory and practice of item analysis, but as these are rather specialized topics they will not be discussed in the present context.

The discussion centred on Fig. 5.1 stressed the fact that for any particular αPS numerical values for the M_{tr} statistics can only be obtained from the use of problems having D_{tr} values of less than ${}_c D_{tr}$ while the continuance statistics \bar{i}_s , V_{ts} , etc., have to be studied by using problems having D_{tr} values greater than ${}_c D_{tr}$. It may not be obvious that attempts to investigate the M_{qr} statistics too can only be useful if they are confined to observations of the outputs resulting from inputs having a restricted range of D . In the region $D_{tr} > {}_c D_{tr}$ a proportion of both potential O_r and potential O_w outputs will be lost because of the intervention of αST , but the losses may be unequal if the numerical values of the M_{tr} statistics are different from those of M_{tw} . The ratio $N_r/(N_r + N_w)$ in this region does not necessarily define the statistic q_r , therefore, but only the interaction of the M_{qr} and M_{ts} statistics (where N_r and N_w are the number of O_r and O_w responses observed at a particular D_{tr} value). Data relevant to M_{qr} and $f(D, K)_{qr}$ can thus be collected only at D_{tr} values of less than ${}_c D_{tr}$ for each PS .

An Experimental Investigation

The discussion so far has rested on the logical development of a set of premises. It would lose most of its force if experiments should show, for example, that in the human problem-solver K_{tr} , K_{qr} , and \bar{i}_s , etc., were all very highly correlated; or that it was impossible to find forms for the various functions $f(D, K)$ which could be applied equally to all individuals (or at least to useful sets of individuals). At this stage it is therefore necessary to consider the results of some experimental work. Although a number of interim reports have been made, covering the gradual development of these experiments (Furneaux, 1948, 1950, 1952, 1955) no readily available account has previously been published. The exposition to be given here will therefore embody rather more detail than would usually be expected in a publication of this type. There appear to be no previous accounts of work directed to the kind of scaling problem which arises when the complications due to the effects of continuance are taken into account. The results of the analysis, moreover, are felt by some psychologists to be rather unexpected. Both these considerations reinforce the argument in favour of a reasonably detailed description.

The particular experiment which is to be discussed was performed with the help of two hundred and

thirty-five soldiers, covering an age range of from 18 to 30 years, with a mean of 19.4. All had previously taken Anstey's Dominoes-Test, and the group had been selected to provide a roughly rectangular distribution between the limits of score defined by the points $+2.0\sigma$ and -1.5σ , derived from the standardization distribution of this test. The upper limit was imposed by the failure to collect together a sufficient number of individuals having very high scores. The lower limit was deliberately chosen because of the need to use only subjects who were reasonably literate, and who could follow fairly complex instructions without too much difficulty. Each subject attempted letter-series problems of the kind used by Thurstone in his P.M.A. battery. Items had previously been scaled for "difficulty" in a rough-and-ready fashion, and were presented in cycles such that within any set of about five consecutive problems a very wide range of difficulty would be encountered. Instructions were designed to encourage high motivation, and the evidence suggests that this was achieved. Stress was laid on the need to persevere with items found to be difficult, rather than to attempt to reach the end of the test. All problems had to be worked through strictly in sequence, and once an item had been abandoned it could not be attempted again. An answer or a dash, signifying abandonment, was required in respect of each problem, and the time required for each response was measured to an accuracy of about two seconds, by using a device similar to that employed by Slater (1938). Testing was carried out in groups of about twenty, over a total time of three hours for each group. This was split up into two morning sessions of forty-five minutes each, separated by a fifteen minute rest period, followed by two similar periods after a break of one and a half hours for lunch.

Various corrections had to be made to the measured response times in order to eliminate the time spent recording answers and reading the timing device from the actual problem-solving time. These were made in terms of data derived from subsidiary experiments made on the same subjects. Corrected response times will be denoted by the symbols t_r , t_u , and t_s as heretofore. Of the two hundred and thirty-five problems available for presentation one hundred and twenty were attempted by every subject, and provided the basis for the analysis. A conventional item-analysis of these one hundred and twenty problems resulted in the rejection of forty. For the total experimental group the correlation between number right within the set of eighty surviving items, and Dominoes score, was 0.84.

If the investigation of the D_{tr} scale and its associated function $f(D, K)_{tr}$ are considered first, the object of the analysis must be to arrange as many as possible

of the usable problems along a scale, and to find a function $f(D, K)_{tr}$, relating \bar{t}_r and D_{tr} , which is equally valid for all subjects once each has been allocated his appropriate value for K_{tr} . In conducting this analysis we must take account only of responses at values of D_{tr} such that the observed M_{tr} statistics have not been affected by the interaction of continuance, i.e. all inputs considered must be $I_{u(tr)}$. We can only define such inputs rigorously, however, after a D_{tr} scale and a suitable form for $f(D, K)_{tr}$ have been evolved, and the associated M_{tr} statistics investigated. The escape from this circle of frustration lies via a series of iterations based on successive approximations. In order to simplify the description of the analysis the present tense will be used throughout.

Design of a D_{tr} Scale. Stage 1

For each of the eighty problems compute the proportion of the total experimental group who responded with O_r . Pick out, say, ten problems for which this proportion is highest, i.e. in conventional terms, the ten easiest problems, and assume that they will also have very low scale values for D_{tr} . These are thus problems which are unlikely to constitute $I_{a(tr)}$ inputs except in the case of subjects who have exceptionally poor continuance, or who are exceptionally slow. It will be convenient to refer to them as the *reference problems*.

For each subject who has returned an O_r to at least five of the reference problems compute the mean of the values of t_r relevant to these problems. This is not a \bar{t}_r measure, since it is unlikely that all the reference problems will turn out to occupy the same D scale position. It provides, in fact, a very rough-and-ready type of K_{tr} measure, say k_{tr} . A subject who has returned only a few O_r responses within the set of reference problems might well owe a high proportion of these successes to guessing, and would in any case receive only a very unreliable k_{tr} score from such a small number of responses—hence the rather arbitrary restriction with which this paragraph opens.

Let us now assume that for every subject, every type O_s response has equal status as a measure of t_s , contributing to an assessment of \bar{t}_s . Suppose that \bar{t}_s is not a function of D_{tr} , and compute \bar{t}_s for every subject. Pick out those whose continuance, thus computed, is above the mean. Other things being equal these subjects will have their values of critical-difficulty (cD_{tr}) fairly high. There is thus a reasonable chance that the “easy” reference problems will all constitute type $I_{u(tr)}$ inputs for each of them.

From these continuant subjects pick out the forty with the lowest k_{tr} scores (i.e. the fastest) and designate these “Group F.” Pick out the forty next in order, i.e. those of moderate speed, and designate these “Group M.”

The most convenient function to use in defining a D scale calibrated in terms of t_r values is obviously of the form—

$${}_a\bar{t}_r = mD_{tr} + {}_aK_{tr} \quad (2)$$

where m has any convenient value. Assume that this function applies to each member of Group M, then it will follow that—

$$t_r(Av)_M = mD_{tr} + {}_MC_{tr} \quad (3)$$

where ${}_MC_{tr}$ is the mean of all the values of K_{tr} relevant to the group members, and $t_r(Av)_M$ is the average value of t_r , within Group M, relevant to any problem which constitutes an input $I_{u(tr)}$ for all the members of the group. Since it is only the relative scale positions of items that are important, and not their absolute positions, we can decide to try the effects of adopting a scale such that in (3) above—

$$\begin{aligned} {}_MC_{tr} &= 0 \\ m &= 1 \end{aligned}$$

i.e. we take the $t_r(Av)_M$ values as being also the D_{tr} values of the ten reference problems concerned.

Still on the assumption that the form of $f(D, K)_{tr}$ is identical for all subjects of Group M we can now compute the value of ${}_aK_{tr}$ for each subject, in terms of the nucleus of the D_{tr} scale provided by the ten reference problems. For each ${}_aS$ (subject) we have—

$${}_aK_{tr} = \Sigma({}_p\alpha t_r - {}_pD_{tr}) / {}_a n \quad (4)$$

where one value of $({}_p\alpha t_r - {}_pD_{tr})$ is derived from each correctly solved item, p , from among the reference problems, and ${}_a n$ is the number of such correctly solved items. If we assume for the moment that the value of the range H_{tr} (Fig. 5.1) is not a function of D_{tr} , then the value relevant to each subject is estimated by subtracting his smallest value of $({}_p\alpha t_r - {}_pD_{tr})$ from his largest value, while the value of $(R_t + H_{tr})$ is approximated, for each subject at $D_{tr} = 0$, by the largest of the values of $({}_p\alpha t_r - {}_pD_{tr})$. It is easy to pick out the smallest observed value of t_s for each subject, and to assume that this gives an estimate of S_t (Fig. 5.1). The value of ${}_cD_{tr}$ for any subject is then that value of D_{tr} at which—

$${}_D=0(R_t + H_{tr}) + {}_cD_{tr} = S_t \quad (5)$$

$$\text{i.e. } {}_cD_{tr} = S_t - {}_D=0(R_t + H_{tr}) \quad (6)$$

If, on computing this statistic, it were to turn out that for several subjects it had a value appreciably lower than the highest of the D values assigned to the reference problems, then it would follow that an appreciable proportion of the t_r data, derived from these problems, were relevant to $I_{a(tr)}$ inputs and not $I_{u(tr)}$. As has been explained, values of D_{tr} assigned to problems in terms of such data are quite useless for purposes of scale construction, and the observed

M_{tr} statistics are specific to the subject concerned, having no general validity.

In "Group M," however, the lowest value of ${}_cD_{tr}$ comes out to be 123, whereas the highest D value associated with a reference problem is 58. All inputs can therefore be assumed, with reasonable confidence, to have been of type $I_{u(tr)}$. If the form for $f(D, K)_{tr}$ assumed for equation (2) is universally applicable, it then follows that in any other group for which all the reference problems constitute $I_{u(tr)}$ inputs, the values of $t_r(Av)$ relevant to each of these problems, if plotted against their appropriate D_{tr} values, must define a straight line of slope 1.0 within the limits of sampling error. Group F, which has already been defined, constitutes such a group, for the average value of t_r for its members turns out to be a little higher than that for group M, and, by definition, they are also appreciably faster. On plotting the relevant data the best-fitting straight line has a slope of 0.74. A substantial part of the error variance of the array about this line is, of course, produced by the variance of K_{tr} between individuals. On subtracting this component and testing the significance of the difference between the two slopes we emerge with $p = 0.03$ (Snedecor, 1948). The plot strongly suggests, in fact, a curve having a negative acceleration. The form for $f(D, K)_{tr}$ assumed in equation (2) does not therefore provide an acceptable basis for the construction of the D_{tr} scale required.

Faced with such a result the next step must involve the formulation of a possible alternative form for $f(D, K)_{tr}$. The search is not, of course, a blind one, but can be guided by suitable graphical trials, and, in the present case, by hints obtained from other investigations. In 1948 (Furneaux, 1948) and 1950 (Tate, 1950) results were reported which showed that a logarithmic transformation of the response-time data relevant to problem-solving attempts resulted in improved homogeneity of variance between subjects. It seems reasonable therefore to try the effect of such a transformation in the case of the experiment now being reported, particularly as graphical inspection of the data suggests that it might be efficacious.

Design of D_{tr} Scale. Stage 2

Let $\log_{10} t_r = T_r$, then the revised form for equation (2) becomes—

$${}_aT_r = mD_{tr} + {}_aK_{Tr} \quad (7)$$

The analysis now proceeds as from equation (2) in Stage 1, all statistics being concerned with values of T_r instead of t_r . The most suitable value for m , equations (2) and (3), is again 1.0, and the crucial stage is again the final check as to whether this statistic comes out to have the same value in group F as was specified for it in group M.

In the experiment being discussed this test produces a numerical value of 1.08. The analysis can therefore proceed on the assumption that equation (7) provides at least a reasonable approximation to the $f(D, K)_{tr}$ form required, over the range of K_{Tr} , defined by groups F and M.

Design of D_{tr} Scale. Stage 3

For every subject in the experimental group a value of ${}_aK_{Tr}$ can now be computed, using his O_r responses to reference problems according to the method described in Stage 1. His value of ${}_cD_{tr}$ is then calculated, again using the assumptions and methods of Stage 1. Those subjects for whom ${}_cD_{tr}$ is smaller than the largest D_{tr} value allotted to a reference problem are discarded, and analysis is continued with the remainder. For every subject retained there is an array of ${}_aT_r$ values, relating to all the O_r responses made to the eighty problems being investigated. From each such value of ${}_aT_r$ subtract the value of ${}_aK_{Tr}$ relevant to the subject concerned. All arrays are thus superimposed at the point $D_{tr} = 0$, $T_r = 0$, and if equation (7) is in fact of universal application the D value of any problem will be given by—

$$D = T_r(Av) \quad (8)$$

Where T_r is the value of $(T_r - K_{Tr})$ obtained from any one subject in respect of the problem concerned, and $T_r(Av)$ is the mean value of T_r for the whole experimental group. The transformation from T_r to T_r is necessary to correct for the fact that the sample of subjects obtaining O_r responses differs from problem to problem in a way which is a function of the D_{tr} value of the problem.

By comparing the D_{tr} values thus allocated with the ${}_cD_{tr}$ values of each subject it will now be observed that for nearly all subjects some of the T_r values contributed to these determinations of D_{tr} were relevant to $I_{u(tr)}$ inputs. A series of iterations are thus necessary to remove such data, and their effects, from the analysis. At the conclusion of this process a D value of probably moderate accuracy will have been assigned to the majority of the eighty problems. Some, however, will have D values greater than the value of ${}_cD_{tr}$ relevant to even the fastest and most continuant of subjects, and thus can only be calibrated as having D_{tr} values greater than such and such. For a similar reason others will have to be calibrated in terms of only a very few data, and thus inaccurately.

Design of D_{tr} Scale. Stage 4

It is now possible to examine the statistics of M_{ts} in greater detail, with a view to improving the estimates of S_t , and thus of ${}_cD_{tr}$. Since some sort of D_{tr} scale position has been allocated to most items, and a value of K_{Tr} assigned to each subject, the value of

D_{tr} at which the time t_i becomes equal to the time $(S_i + H_{ts})$ can be computed. This gives the numerical value of ${}_cD_{ts}$ for each individual, and by taking account only of those t_s values relevant to O_s responses evoked by problems for which $D > {}_cD_{ts}$ it becomes possible to investigate M_{ts} .

Assume again that \hat{t}_s is not a function of D_{tr} , and compute V_{ts} for each subject, using only $I_{u(t_s)}$ inputs as defined above. The application of Bartlett's test now shows these variances to differ significantly from one individual to another ($\chi^2 = 310, p \approx 0.01$ with 228 d.f.). On introducing the transformation $\log_{10} t_s = T_s$, however, homogeneity is achieved ($\chi^2 = 242, p \approx 0.30$). Compute \hat{T}_s for each subject, and then the values of \hat{T}_s obtained by subtracting \hat{T}_s from each available value of T_s . All M_{T_s} distributions are thus superimposed with $\hat{T}_s = 0$. Collect together all the values of \hat{T}_s relevant to each particular problem, and compute their mean, $\hat{T}_s(A_t)$, for the whole experimental group. On correlating $\hat{T}_s(A_t)$ with D_{tr} over the whole set of problems we find a coefficient of 0.11 which with 31 d.f. is not significant. The assumption that T_s , and thus t_s , is not a function of D_{tr} seems therefore to be justified.

The method of timing used for the measurement of response times was such (Slater, 1938) that it is easy to find out how long a subject had already been working for when he attempted each problem. It is thus possible to plot each value of \hat{T}_s contributed by each subject against this time already worked, and to see whether continuance varied appreciably during the time that testing was in progress. On plotting a single array including all \hat{T}_s values derived from the whole group it becomes clear that no important variations occurred save during the concluding twenty minutes of both morning and afternoon testing periods. During each of these periods there is a steady fall in the values of \hat{T}_s , and an increase in the variance of the array. On further investigation this increase in variance is found to reflect the fact that subjects with high scores in the Dominoes test maintained their continuance virtually unchanged throughout the whole of each testing period, while those with low Dominoes scores were responsible for the general downward trend. The need to take account of variations in continuance would add formidable complications to the analysis, and to avoid these all data relating to the last twenty minutes of testing, in both morning and afternoon, are deleted from the analysis, for all subjects. After this has been done and revised values of V_{T_s} calculated, Bartlett's test gives $\chi^2 = 231, p \approx 0.40$ with 220 d.f.¹, the best estimate of V_{T_s} being 0.0144 log sec.

The pooled distribution of \hat{T}_s , covering all subjects,

¹ At each stage of the analysis a few subjects fall out because of the nature of their test responses, scores, etc.

can now be taken as analogous to the M_{T_s} distribution that would result from a single subject of constant continuance who attempted a very large number of problems. There will be a small additional component of variance resulting from the sampling error associated with each individual determination of \hat{T}_s , but this will not be sufficiently large to produce any great distortion of the shape of the pooled distribution. On inspection this is clearly of normal type, so that it is reasonable to conclude that values of T_s which approach the extremes S_i and $(S_i + H_{ts})$ arise rather infrequently for any subject. The effective minimum value of \hat{T}_s will in fact have a value of about $\hat{T}_s - 2\sqrt{V_{T_s}}$ for everyone, at all values of D_{tr} . Values of ${}_cD_{tr}$ computed in terms of this revised estimate of the minimum value of \hat{T}_s , for each subject, are of course higher than those resulting from the values of S_i previously used, so that a larger number of $I_{u(t_r)}$ become available for every subject. Iterations from this point result in revised values of D_{tr} for some problems, and in revised values of K_{Tr} for all subjects—all based on an increased number of data.

Design of D_{tr} Scale. Stage 5

If we take any two problems, p and q , and for each subject for whom they both constitute inputs $I_{u(t_r)}$ compute ${}_pT_r - {}_qT_r = ({}_p - {}_q)\hat{T}_r$, then if the value of V_{Tr} associated with each problem is equal, and is the same for all subjects, the variance of $({}_p - {}_q)\hat{T}_r$ within the whole group of subjects should equal $2V_{Tr}$. Starting with the problem having the lowest D value specify pairs of items of successive D_{tr} scale positions. For each pair compute the $({}_p - {}_q)\hat{T}_r$ variance within the total group, but taking account only of values derived entirely from inputs $I_{u(t_r)}$.

Testing the resulting values for homogeneity the experimental data being considered give $\chi^2 = 45.7, p \approx 0.04$ with 31 d.f. (Bartlett). The hypothesis that V_{Tr} has the same numerical value for all $I_{u(t_r)}$ is thus untenable. On further investigation, however, it appears that the lack of homogeneity results from exceptionally large values of $2V_{Tr}$ associated with two particular problem pairs. On deleting these and repeating Bartlett's test on the remainder, we obtain a χ^2 of 36.1, i.e. $p \approx 0.18$ with 29 d.f.

Now, compute separately within each subject, the variance of all the $({}_p - {}_q)\hat{T}_r$ values which arise from all those problem-pairs which constitute $I_{u(t_r)}$ inputs, but ignore the two pairs deleted from the analysis above. On testing for homogeneity between subjects we find $\chi^2 = 227, p \approx 0.4$ with 216 d.f. The variance estimate derived from the between-pairs-analysis was 0.1320, while the between-subjects-analysis gives a value of 0.1292. These clearly do not differ significantly, and their mean, 0.1306 log sec, provides an estimate of $2V_{Tr}$.

The analysis has provided no evidence inconsistent with the hypothesis of a numerical value for V_{Tr} which is constant over both subjects and problems, save in the case of one or both of the members of the two deleted problem-pairs. One can, however, imagine rather complicated (and unlikely) relationships between V_{Tr} and D_{Tr} on the one hand and K_{Tr} on the other, which might also explain the results. No attempt will be made to dispose of them, in the present context, but the hypothesis of constancy will be accepted as being the simplest explanation of the data.

Up to the time of writing no rigorous analysis has been made of the exact form of the M_{Tr} distribution, but graphical inspections suggest that it is of normal type at all values of D_{Tr} and for all subjects. Response times as long as $(R_t + H_{Tr})$, at any value of D_{Tr} , will therefore be rare, and the value of D at which any appreciable proportion of inputs turn out to be $I_{a(Tr)}$ will therefore be rather higher than ${}^cD_{Tr}$ as so far estimated. If the effective upper limit is taken to be $K_{Tr} + 2\sqrt{V_{Tr}} + D$, at any value of D , then a revised value of ${}^cD_{Tr}$ can be computed for each subject. This revision will produce an increase in the

FIG. 5.3. $\dot{T}_r(Av)$ PLOTTED AGAINST $100D_{Tr}$ FOR GROUPS OF VARYING SPEED
(See text.)

Note. The curves A, B, C, D show the relationships to which the data should conform: they are *not* the best-fitting straight lines. To facilitate the examination of this graph 1.5 log units have been added to each value of $T_r(Av)$ in Group D, and values of 1.0 and 0.5 log units in Groups C and B respectively.

number of $I_{u(tr)}$ available for each person, and thus provides the starting point for further iterations. When these have been completed final values of K_{Tr} and \bar{T}_s are available for all subjects, and final estimates of D_{tr} for each problem.

A crucial test is now possible to see whether equation (7) is acceptable as the form of a relationship between D and \bar{T}_r which is equally applicable to all subjects. Divide all subjects into four approximately

FIG. 5.4. DISCREPANCY BETWEEN RELATIONSHIP OF \bar{T}_r TO D WHEN I_a INPUTS ARE USED, AND THAT APPLYING TO $I_{u(tr)}$

The straight line A gives the relationship applying in the case of $I_{u(tr)}$ inputs. Each point plotted shows the median observed value of \bar{T}_r which relates to the set of inputs I_a having values of D_{tr} within the range ± 10 of the central value shown. The vertical lines terminate at the values of the upper and lower quartiles.

Values of \dot{D}_{tr} have been multiplied by 100

equal subgroups in terms of their K_{tr} scores, the fastest being allocated to Group A, the slowest to D, and the remainder, in order, to the intermediate groups. For each subgroup compute the value of $\bar{T}_r(Av)$ relevant to each problem, and plot these values against the D values of these problems. For each subgroup separately the slope of the relevant best-fitting straight line should have a value of 1.0.

It will be clear from Fig. 5.3 that such a result was actually observed in the case of the experimental group concerned, so that the hypothesis that the relationship between D and \bar{T}_r has the form set out in equation (7) for every subject is supported. The evidence presented in Stage 4 of the analysis also supported the hypothesis that the value of V_{Tr} is independent of D , and identical for all subjects. It must be remembered, however, that this latter result was only demonstrated after two item-pairs had been deleted from the analysis. Subsequent examination showed that one item from one of these pairs should have been rejected at the stage of item analysis; a correlation of 0.04 with the criterion score had been wrongly computed as one of 0.40. It was hoped that this initial item analysis might define a set of items all more or less of the same type, using this last term in

the rather unorthodox manner suggested earlier in the discussion. The results of the analysis, and the accidental finding with the wrongly calibrated item, suggest that this was in fact accomplished. Since it will be shown, in the further analysis, that separately designed D_{tr} and D_{qr} scales correlate very highly, this is more or less what one would expect to find, since a conventional item-analysis is clearly an approximate method of classifying in terms of M_{qr} characteristics. It achieves this classification only approximately, however, since it makes no distinction between O_{10} and O_s responses.

In the second discrepant item-pair the non-homogeneous value of $2V_{Tr}$ was found, on investigation, to be associated with one of the two items, rather than both, but no explanation for the discrepancy has as yet been found.

It must now be shown that the deletion of $I_{u(tr)}$ responses was necessary, and that their retention would have produced the kind of complication predicted by the theoretical analysis of a PS . If $I_{u(tr)}$ inputs give rise to the same relationships between \bar{T}_r and D_{tr} as have been demonstrated for $I_{u(tr)}$ inputs, then the effort to distinguish between the two kinds is clearly unnecessary, and the theory which calls for the distinction is unsound.

For every subject compute the values of \bar{T}_r which relate to $I_{u(tr)}$ inputs in the same way as was used for type $I_{u(tr)}$. For each subject separately, compute the values of \dot{D}_{tr} which apply to all these inputs, where $\dot{D}_{tr} = D_{tr} - cD_{tr}$. All such inputs are thus re-scaled in terms of a D scale which has its zero at that point on the D_{tr} scale above which continuance should, in terms of the theory being examined, begin to distort relationships. On plotting \bar{T}_r v. \dot{D}_{tr} as a single array covering all subjects, the relationship graphed in Fig. 5.4 is obtained. If $I_{u(tr)}$ inputs behaved in the same way as do type $I_{u(tr)}$ this array would have defined a straight line of slope 1.0. As it clearly does not, the distinction between the two kinds of input appears to be justified. The nature of the array is in fact exactly of the kind that would have been predicted in terms of the discussion on pp. 175-176, both slope and dispersion decreasing as \dot{D}_{tr} increases. When interpreting Fig. 5.4 it is important to bear in mind the fact that the problems which, as $I_{u(tr)}$ inputs, gave rise to this array are the same problems which, as $I_{u(tr)}$ inputs, led to the relationships shown in Fig. 5.3.

The results of the analyses justify the retention of the hypothesis that m , equation (7), and V_{Tr} are population constants. It is convenient to replace equation (7) by—

$$\bar{T}_r = mD_{tr} + K_{Tr} + \varepsilon_i \quad (9)$$

where ε_i is a positive or negative component arising

on a particular occasion i , such that at every value of D the values of ε relevant to a large number of occasions are distributed with variance V_{Tr} about zero as mean.

Some psychologists, when discussing this hypothesis with the writer, have expressed surprise that such invariances should be found in a field where the discovery of substantial individual difference is the normal expectation. In the present study, however, such differences do not disappear, but are taken up in the individual-constants K_{Tr} and T_s which vary very considerably from one person to another. Equation (9) provides a form of relationship analogous to that embodied in, say, Fechner's law, which latter has served to clarify, rather than obscure, the study of individual differences in sensory thresholds. Equation (9) does, however, assert that there may be some cerebral mechanism involved in problem-solving activity, which is of the kind used in connexion with letter-series problems at least, and which has much the same form for at least a very wide range of individuals.

A Possible Problem-solving Mechanism

While the writer was speculating on the possible implications of these findings a report was published of a paper read by Hick (1950). In this paper Hick showed that the relationship between the time taken to react within a multiple-choice situation and the complexity of the choice situation could be expressed as—

$$RT = K \log M$$

where RT = choice reaction-time

K = an individual constant

M = a function of the complexity of the choice situation.

He developed the argument that this is the relationship one would expect to observe if multiple-choice activity involved successive binary classifications. As the brain seems to consist of a vast number of nearly identical units he argued that it might be permissible to posit that all its activities involve sequences of elementary operations of like kind and duration. Such a device might well function by carrying out successive binary switchings, with each "switch" taking the same time and involving the same sort of simple basic activity. This hypothesis of Hick's seems to imply that multiple-choice reaction-time is a measure of the time required for a search to be completed in the brain for the set of "connexions" which would initiate a required behaviour. It then occurred to the writer that problem-solving should perhaps be regarded as a special case of a multiple-choice reaction, and that it

would be interesting to see if the rather striking characteristics of equation (9) could be explained by postulating, within problem-solving processes, the repeated occurrence of some elementary activity which requires a substantially constant time for completion. The following hypothesis was eventually developed.

The brain structure of any individual, P , includes a set of ${}_pN$ neural elements which participate in problem-solving activities. It is not necessary at this stage to adopt any particular view as to the nature of these elements, which might be either single neurones or much more complex structures. The solution of a particular problem, h , of difficulty D , involves bringing into association a particular set, ${}_pN_h$, of these elements, interconnected in some precise order. (The terms "bringing into association" and "inter-connected" should not necessarily be interpreted literally after the manner of, say, an electrical circuit. For example, the almost simultaneous firing of two otherwise independent units could constitute one method of bringing them into association, provided some device existed which could detect the simultaneity, while the exact order of firing might represent the mode of interconnexion.) When problem h is first presented single elements are first selected, at random, from the total pool ${}_pN$ and examined to see whether any one of them, alone, constitutes the required solution. A device must be postulated which carries out this examination—it must bring together the neural representations of the perceptual material embodying the problem, the rules according to which the problem has to be solved, and the particular organization of elements whose validity as a solution has to be examined. It must give rise to some sort of signal, which in the case of an acceptable organization will terminate the search process and will initiate the translation of the accepted neural organization into the activity which specifies the solution in behaviour terms. Alternatively, if the organization under examination proves to be unacceptable a signal must result which will lead to the continuation of the search process. It will be found useful to refer to this hypothetical device under the name of "the comparator."

If $D \neq 1$, the comparator will reject each of the ${}_pN$ trial solutions involving only a single element, and the search will then start for a pair of elements, which, when correctly interconnected, might constitute a valid solution. Suppose $D \neq 2$, then all possible organizations of the ${}_pN$ elements taken two at a time will also be examined and rejected, after which we can imagine that the search will continue among sets of three, four, five, etc. If $D = r$, then the comparator will reject in turn all the organizations involving from 1 to $(r - 1)$ elements, so that there will be a time

$\tau \sum_{r=1}^1 E$ sec within which a solution cannot occur, where—

τ (Tosouton) = the time required for completing a single elementary operation within the search process.¹

$\sum_{r=1}^1 E$ = the number of elementary operations involved in the search process up to the level of complexity ($r - 1$).

Similarly, after a time $\tau \sum_{r=1}^1 E$ sec all possible organizations embodying r elements will have been examined, so that correct solutions to problems of difficulty r will always arise within the period defined by the two limiting times $\tau \sum_{r=1}^1 E$ and $\tau \sum_{r=1}^1 E$. In terms of such a hypothesis, therefore, V_{Tr} is in no sense a function of error of measurement but results mainly from the range of times required to set up all possible modes of neural organization at a particular level of complexity. It is perhaps worth noting, in passing, that within the framework of such a hypothesis error would be accounted for by positing that during the search process organizations arise at levels of complexity $r - \delta_1, r - \delta_2, \dots$, etc.,² which satisfy most, but not all, of the requirements of a true solution to a problem of difficulty r . If the comparator has characteristics analogous to those of "band-width" in electrical and mechanical discriminators, i.e. if its discriminating powers are such that neural organizations which closely resemble the organization representing a correct solution may be accepted as the required organization, then the possibility of error arises. The frequency of error, thus conceived, will be a function of the band-width of the comparator, and since the number of "nearly-correct" organizations will increase as D is increased, the likelihood of error will increase with D .

This probability is clearly dependent on the exact nature of the search process. Finally, continuance is easily defined in terms of such a "search" hypothesis; it is a measure of the length of time during which, following the initiation of search, the comparator remains "set" for a particular problem.

As has been explained, the hypothesis thus summarized seemed to grow naturally upon the foundations laid down by Hick, working with reaction-time data. It has the merit that it can be checked experimentally in virtually all its aspects, relationships of

time against complexity which would characterize such a process can readily be computed, and compared with those actually observed. It can only be stated here that if it be considered that the search mechanism operates by setting up the orderly sequence of events outlined above, but takes account only of combinations rather than of possible permutations of neural organization, then time-complexity relationships approximating to those defined by equation (9) do in fact emerge. In the simplest, completely orderly case the observed distribution of log-times at a particular value of D should, of course, be rectangular rather than normal. This disparity between the requirements of the theory and observation can be removed by postulating that as time elapses after the initiation of the search for a particular solution the number of neural elements involved in successive interconnexions tends to increase steadily, but that interspersed with successive combinations involving a particular value of D, N_h there also occur organizations involving either a larger or a smaller number of elements. In other words, an element of randomness must be imposed upon the type of order defined by the theory. It is interesting to note that if this is done then the theory predicts that with very low values of D , V_{Tr} should tend to increase as D decreases. This prediction from the theory has been confirmed by observations subsequently made. It is also of some interest that, if the theory is approximately true, then the solution of letter-series problems of such difficulty that they are correctly solved by only about 5 per cent of the unselected adult population involves the activity of less than one hundred neural elements.

A theory of this kind should not, of course, be taken too seriously. It might, for example, be objected that introspection during problem-solving reveals nothing comparable to the postulated search process, but then neither does visual experience in any way suggest the underlying complicated retinal and central processes. A more telling argument would be that it simply replaces the problem-solver by a little mannikin, the comparator. It could perhaps be claimed that it does serve the functions that a theory should, i.e. it accounts for such data as have been collected, suggests new experiments which could profitably be attempted, and predicts results for some of them.

One obvious prediction is that a change in the value of τ , such as one might expect to result from, say, an increase in drive, should leave unchanged the values of m and V_{Tr} , equation (9). A set of fifteen problems (set A) was therefore assembled, all having approximately the same low D_{Tr} scale position, and a further set, B, all clustering around a slightly higher position. According to the theory, any group of subjects, no matter what their drive-state, should give rise to exactly the same value for $T_r(Av)_B - T_r(Av)_A$, where

¹ The Greek $\tau\omicron\sigma\omicron\upsilon\tau\omicron\nu$ (Tosouton), meaning "so long," seems to be an appropriate name for this elementary period, particularly since τ is very appropriate as a symbol for a short period of time.

² If the possibility be accepted that the comparator might sometimes fail to respond to the "correct" organization, then response might also occur at levels of complexity $r + \delta$.

the two terms subtracted are the mean values of \bar{T} relevant to the two sets of items, within the group concerned. This prediction has now been confirmed (within the limits of sampling error) for six different groups of university students, all comprising between thirty and seventy subjects, and covering a range of Faculties and ages. It has also been confirmed for one group of three hundred boys having a mean age of 14.4 years, in English grammar schools. For some of these groups the instructions given have stressed the fact that problems should be tackled at a comfortable, easy pace, while for others the fastest possible rate of work has been demanded. In every case adequate practice has preceded the actual testing.

V_{Tr} has behaved according to expectation in all those groups which have attempted the problems under what have come to be known as *unstressed* conditions, i.e. working at their own preferred pace. An appreciably discrepant value has been observed, however, in one of the groups of university students who were working under *stressed* conditions, i.e. at maximum rate. For this group the mean value of V_{Tr} among its members was significantly higher than expected. At the time of writing several lines of evidence appear to be converging to support the hypothesis that individuals who are working under a degree of drive in excess of that required for optimum performance in the task, display such exaggerated values of V_{Tr} . This single discrepancy may indicate an instability in the value of τ under such conditions.

The Investigation of M_{tw} and M_{qr}

Another prediction from the theory is clearly that the dispersion of the response-times arising in connexion with O_w outputs should be greater, at any value of D_{tr} , than that characterizing O_r outputs, since the former can arise at several levels of complexity, the latter only at one. Nothing has so far been said about the experimental investigation of the M_{tw} statistics, or of those of M_{qr} , nor of the problems which arise in connexion with the investigation of the associated functions $f(D, K)_{tw}$ and $f(D, K)_{qr}$. Space does not permit any detailed discussion of these topics. The general strategy used, a succession of iterations having the object of eliminating I_u inputs and of finding acceptable forms for the relevant functions $f(D, K)$, has been identical with that already described, but some of the detailed tactics have had to be modified. It must suffice to report of the M_{tw} statistics that values of \bar{T}_w are smaller than values of \bar{T}_r at the same D_{tr} value, the discrepancy increasing as D increases. Similarly, V_{Tw} is larger at all values of D_{tr} than is V_{Tr} , and again, the difference is greatest at high values of D . It is encouraging that these are just the characteristics which would be expected to arise from a device such as has been postulated. The

numerical values of these statistics, however, seem to be subject to a degree of individual variation which it has not yet proved possible to describe in terms of a few simple $f(D, K)$ relationships. In view of this failure the M_{tw} statistics cannot as yet be summarized in terms of scores which have the same significance for all subjects. In the particular groups of soldiers studied the correlations between \bar{T}_r and \bar{T}_w , at various low values of D_{tr} , ranged around 0.58. At high values they fell below 0.50. These values, and the differences between them, reflect in part the low reliability of the \bar{T}_w scores; resulting partly from the high value of V_{Tw} and partly from the fact that, at low values of D_{tr} , a comparatively small number of O_w responses are available for the making of \bar{T}_w assessments. They do serve to make it clear, however, that the temporal characteristics of incorrect responses do not provide a very good estimate of those for correct ones, and this underlines the unsatisfactory nature of some frequently used rate measures.

In connexion with M_{qr} the analysis has been more successful. Using the D_{tr} scale as a starting point it has been possible to specify a normal ogive which, given an appropriate value of K_{qr} , gives an acceptable fit to the data relating q_r and D_{tr} for each member of the experimental group which has been described. In evolving the relevant function only type $I_{u(tr)}$ inputs were of course taken into account. An attempt to reduce the SE_{ev} of individual arrays about the best-fitting ogive, by altering the D scale values allotted to the various problems, met with very little success, the correlation between the D_{tr} scale which served as a starting point, and the D_{qr} scale finally evolved, being 0.92. There are thus strong grounds for believing that, with letter-series type problems at least, the ultimate determinants within problems of both response-time and response-quality, are much the same. The use of the term "difficulty" embracing both kinds of D scale, seems thus to be justified. What must not be done, however, is to attempt to calibrate for D by lumping O_w and O_r outputs together as "wrong" and using a simple index such as percentage of wrong answers in a defined group. It will be clear that this procedure will result in the formation of an unstable scale of a multi-dimensional kind, because of the intervention of the effects of continuance. In the group which has been described, a D scale thus derived exhibited a correlation of only 0.68 with the D_{tr} scale when computed within the Group D relevant to Fig. 5.3, whereas for Group A, pertaining to the same figure, the coefficient rose to 0.79.

Interrelationships among Scores

The demonstration that D_{tr} and D_{qr} scales are very closely related does not imply a similar high correlation between values of K_{Tr} and K_{qr} for individuals.

Data relating to this latter relationship, and to those involving \bar{T}_s as well, are given for the experiment which has been described, in Table V.1. From this it will be clear that these are all relatively independent

TABLE V.1
INTERCORRELATIONS OF K_{Tr} , K_{qr} , AND \bar{T}_s

	K_{Tr}	\bar{T}_s
K_{qr}	— 38	31
\bar{T}_s	— 27	

Notes: (a) A high value of K_{Tr} implies low speed.
 (b) A high value of K_{qr} implies high accuracy
 (c) A high value of \bar{T}_s implies high continuance.
 (d) Of the total experimental group, only two hundred and nine could be scored for all three attributes.

scores which demand separate consideration. In more highly selected groups, such as university students, the coefficients concerned, as would be expected, are found to be considerably smaller. One cannot therefore justifiably talk of "letter-series test ability," but only of a person's standing in terms of each of the scores K_{Tr} , K_{qr} and \bar{T}_s . It seems difficult to resist the conclusion that results of a similar kind would be obtained if other types of problem material were investigated. Instead of intercorrelating conventional test scores, therefore, and describing cognitive structure in terms of such correlations, it seems that the foundation data for such analyses should be properly constituted measures of speed, accuracy and continuance, derived from each of the kinds of test material which it is desired to investigate.

It is very difficult to know whether K_{Tr} type scores derived from different kinds of problem material would display high intercorrelations, and thus define a useful speed-factor within all cognitive-test behaviour, since the speed scores used by nearly all those who have investigated this problem have been of the kind criticized in the earlier sections of this discussion. Rimoldi (1951), in a study remarkable for the range of activities it covered, showed that several fairly distinct speed factors were needed to describe his data, motor, perceptual, and cognitive rate measures each defining their own factor. His speed-of-cognition factor was a strong one, and included tests as disparate as "reasoning" and "space," together with measures of free-association rate, recognition rate, and speed of making judgements. On the other hand this cognition factor was only very slightly correlated with a perceptual-speed factor which included rate measures for reading, a verbal-meaning test, and a test of number. Nelson (1953), using reasonably well designed scores, found only very small intercorrelations

within a set of intellectual and motor speed-tests in a normal group, but as this group had a very restricted variance on the intellectual side, at least, this finding is of little significance. (With the "Nufferno" speed measures, for example, her group had a S.D. of about one quarter, of that characterizing an unselected normal population.) Nelson's abnormal groups, neurotics and psychotics, both of which displayed much larger variances than her normals, provided data which defined strong factors of mental and motor speed. In Thurstone's perceptual study (1949) a factor clearly analogous to Rimoldi's speed-of-cognition factor also emerged. There are in addition more than a score of correlational studies which have demonstrated intellectual-speed factors, but using unsatisfactory scoring methods.

The accuracy score (K_{qr}) derived from letter-series tests usually displays correlations with cognitive-test scores of the conventional kind which are higher than those associated with either speed (K_{Tr}) or continuance (C). This is not invariably the case, as everything depends on the relationship between the D values of the test items and the values of cD displayed by those taking them. In practice, however, accuracy does frequently emerge as the score which displays the closest relationships with those of the conventional kind. Since such conventional scores usually display quite high intercorrelations among themselves, this suggests that there may be quite a strong factor of accuracy underlying a wide variety of cognitive performances.

There would thus appear to be quite a strong justification for talking of a subject's *speed* and *accuracy* without making specific reference to the kind of problem-material in terms of which these attributes were measured. So far as continuance is concerned the position is less clear. In so far as test instructions can be designed in such a way that continuance becomes synonymous with persistence the results obtained from factorial studies of persistence tests are clearly applicable (e.g. Ryans, 1938). These investigators have shown that persistence tests do display intercorrelations which are sufficiently high to define a trait, or more probably two related traits. Unless instructions are so devised, however, continuance in a particular test will be affected by so many factors specific to that test that it would not be surprising if the continuance scores evoked by different instruments were only slightly related.

Until recently most psychologists have accepted the view that cognitive and orectic test-scores are relatively independent. A certain amount of evidence to the contrary has been available for some time, such as the work of Mandler (1952) who has shown that anxiety may reduce scores in certain kinds of test. Such demonstrations have usually been regarded as

providing interesting exceptions, under rather unusual conditions, to well-established general rules. The analysis here presented, supported as it is by the results obtained by Mangan (1954) makes it difficult to accept such a viewpoint, since continuance will always involve orectic determinants. It is moreover quite obvious that speed in any problem-solving task will be a function of drive, and even if an increase in a subject's speed were always to be attended by just such a decrease in accuracy¹ as would serve to keep constant the overall score achieved in a conventional test, this would only serve to demonstrate rather clearly the inadequacy of such conventional tests for the purpose of making fundamental measurements.

The interdependence of cognitive and orectic traits seems to be demonstrated by the results of some experiments carried out by the writer in connexion with the relationship between stressed and unstressed speed. By subtracting K_{Tr} (stressed) from K_{Tr} (unstressed) for a particular individual one obtains a score which has been designated stress-gain, and which provides a measure of the extent to which he can improve his rate of production of O_r responses under the stressed instructions. This score was obtained for each of a group of seventy-five university students, who also completed the Guilford S.T.D.C.R. inventory. Taking the (D + C) score as providing a measure of neuroticism (Hildebrand, 1953) and the R score as a measure of extraversion, the whole group was divided up into four subgroups of approximately equal size—stable extraverts (SE), stable introverts (SI), neurotic introverts (NI), and neurotic extraverts (NE). The term neurotic is used here, of course, in a purely relative sense, and so far as is known no individual was actually neurotic in the overt, clinical sense. The mean values of stress-gain within each of these groups are displayed in Table V.2. The largest value is that associated with NE, whereas for NI a

negative value was obtained, indicating a slower rate of work under stressed than under unstressed conditions. The simplest explanation of these results is probably that which assumes that introverted students, because of their greater intrinsic susceptibility to conditioning (Franks, 1957) have come to respond to any formal test or examination situation by generating a high drive. If neuroticism is in any case associated with a state of high drive, then the convergence of the two determinants, within the NI subgroup, will result in such a state of high drive, even under the unstressed conditions, that the further increase produced by the stressed instructions takes it to a value greater than the optimum postulated by the Yerkes-Dodson law, and actually results in a performance decrement. The NE group, on the other hand, will exhibit much less drive under unstressed conditions, increasing to a value nearer to the optimum during the stressed test.

Whatever explanation may be accepted, the results demonstrate clearly that performance in a cognitive-test situation is influenced in very important ways by orectic determinants. A rough distinction between the cognitive and orectic manifestations of a disorder may often be useful, but to use cognitive tests as if they gave information about some independent, encapsulated part of the personality would seem to be a quite unjustifiable procedure. One could in fact go so far as to suggest that the study of the way in which cognitive performance changes under the influence of testing régimes designed to vary such factors as stress, motivation, and the like, should form an essential part of psychometric practice.

The Measurement of "Level"

The detailed design of tests which can be used for making accurate measurements of such individual constants as K_{Tr} and K_{or} will not be discussed here, since the question is considered elsewhere (Furneaux, 1953, 1956). It need only be stated that a set of tests of such kinds have been developed (Furneaux, 1953, 1956) and that the use of these instruments has led to results of the kind which are discussed by Payne in his contribution to this HANDBOOK. Little mention has as yet been made in the present contribution, however, of such attributes as *power* and *level*, nor of the techniques which have been used for their measurement.

There are no generally accepted definitions for either of these terms, and both are frequently used without any attempt at definition being made at all. They are normally treated as if synonymous, and usually as if they referred to scores in untimed tests. It will be clear from the discussion so far that if an untimed test is made up of items constituting $I_{u(tr)}$ inputs for the individual being assessed, then it will constitute a measure of accuracy alone, whereas if a

TABLE V.2
RELATIONSHIP BETWEEN STRESS-GAIN
AND S.T.D.C.R. SCORES

¹ The writer knows of no evidence which indicates that this kind of compensation does in fact occur.

proportion of the items are $I_{a(tr)}$, being difficult for the subject concerned, then the test will measure an interaction of speed, accuracy, and continuance specific to the combination of test and subject. The normal use of the terms power and level thus imputes to the subject nothing more fundamental than the ability to achieve a particular score in a particular test, which may or may not exhibit a high correlation with the score he would achieve in a different untimed test using the same kind of material.

The writer has found it useful to reserve the term *Level-Test* for use in connexion with tests which have deliberately been designed in such a way as to provide the subject with the maximum possible reward for persistent effort (Furieux, 1953). The basic unit in such a test is a set of items comprising a cycle. The first problem in each cycle is very easy, each succeeding item is of greater difficulty than its predecessor, and the last is so difficult that few can solve it correctly even when given unlimited time. The number of items in a cycle is quite small, so that difficulty increases fairly rapidly from item to item. On the initial easy items, score will be a function of accuracy only, but speed and continuance in interaction play an increasingly important part as the later problems are attempted, even for highly able subjects. The total number of items correctly solved within one cycle will thus provide a score for effectiveness within a situation designed to reward high continuance, as well as speed and accuracy, and the test instructions are so designed that continuance depends almost entirely on persistence. The score provided by one cycle will be rather unreliable, being based on a small number of items. If, however, several such cycles are arranged in series, the mean score-per-cycle, computed over all items attempted, provides a measure of adequate reliability. The maximum score possible is the same no matter how few cycles have been completed, so that a time limit can be imposed without penalty to the slow worker. Such a subject, if he is also persistent and accurate, can in fact obtain a higher score than one who is fast but lacks persistence. The reliability of the measurement is the only thing that varies with the number of problems attempted. Level-scores, thus defined, are not altogether free from the kind of ambiguity which has been criticized in connexion with conventional-type intelligence tests, since different level-tests, incorporating different numbers of items per cycle, and covering different ranges of difficulty,¹ will still give rise to scores which are not altogether comparable. It will be clear, however, that this kind of assessment approximates, rather roughly, to a measurement of the maximum

level of difficulty at which the subject can function successfully when motivated to persevere with items experienced as difficult. In so far as this is the case such level-tests measure a reasonably invariant property of the individual. The design and use of such tests is dealt with in greater detail elsewhere (Furieux, 1953 and 1956). They serve the function of indicating the subject's intellectual ceiling, without however providing any clue as to the relative size of the contributions to his effectiveness which are provided by the more fundamental attributes of speed, accuracy, and continuance. In the less disabling forms of schizophrenia, for example, there appears to be a phase during which patients achieve level scores of the same magnitude as those characterizing normal individuals. Their illness has thus not impaired their effectiveness in certain kinds of situation. Tests of speed, however, reveal a marked slowness in the same patients, which is compensated for by an increase in persistence. The latter kind of test thus reveals an important aetiological characteristic, while the former shows that the organism as a whole is able, at least for a time, to compensate for its effects. Both kinds of measuring device would therefore appear to have their part to play in the investigation of abnormal function.

SUMMARY

The thesis has been argued that a subject's score in a cognitive test of the familiar kind is determined by the interaction of a number of determinants which should really all receive separate consideration. A logical analysis of the nature of the problem-solving act suggests that three attributes, speed, accuracy, and continuance, are concerned in any kind of "intelligent" behaviour, and that the valid and unambiguous measurement of these traits can only be accomplished after the problem of classifying problems in terms of both "type" and "difficulty" has been solved. The problem of scaling for difficulty has been shown to be a more complex one than has in general been assumed, and an example has been presented showing the kind of experimental analysis which can be undertaken in an effort to achieve a valid difficulty scale. Once such a scale had been achieved, in the experiment described, it showed up the existence of characteristics of problem-solving behaviour which seem to be invariant as between all subjects, and this suggests that the "mechanisms" involved in problem-solving may have a particular form, which has been described.

Once valid methods of defining the basic attributes of speed, accuracy, and persistence have been evolved, it becomes possible to see how they must interact in different kinds of conventional test, and how these interactions must complicate attempts to understand the nature of cognitive abnormalities. The whole

¹ It should be stressed that, by definition, a level-test *must* include items in each cycle which are experienced as being very difficult by those for whom the test was designed.

chapter should be regarded as providing an introduction to the more detailed discussions presented by Payne, in that it serves to describe concepts and results used by him, but which have not previously been widely reported.

In defining the device *PS* the human problem-solver or subject has of course been grossly over-simplified. Continuance, for example, has been accounted for in terms of a switch *ST* which is either "on" or "off." During the course of a particular attempt to solve a particular problem, however, the subject will presumably manifest a drive state of systematically varying intensity, so that the appropriate analogy is more likely to be a continuously variable impedance interposed between *PB* and its power supply. Again, although the question of between-persons correlations among scores for such attributes as speed, accuracy, and continuance has been touched upon, nothing has been said of the consequences which would arise as a result of within-person correlations between the several kinds of event which participate in determining the nature and characteristics of a particular output. The complications which arise when attributes such as memory, fatigue, conditioned inhibition, and the like, are introduced into the analyses, have not been considered at all.

The early introduction of too great a degree of complication, however, is likely to defeat its own objects, useful trends being obscured by a mass of detail so complex as to defy analysis. At the present time only a few very tentative steps have been taken towards the evolution of a theory of human problem-solving activity, and the present paper represents no more than an attempt to provide the beginnings of a vocabulary, of a conceptual framework, and of a technique of analysis.

The writer believes that the human problem-solver is rather like a self-programming calculator. The effectiveness of such a device depends in part on the characteristics of the computing mechanisms, but also on the adequacy of the programming. If a subject is attempting a highly structured test, such as may be made up of letter or number series, nearly all the programming is, in effect, imposed from outside, by the instructions. Under these circumstances the subject is functioning almost exclusively as a computer, and the characteristics he displays in a "pure" test of this kind are likely to give information about some relatively simple cognitive mechanism. In a more complex situation, however, part of the subject's task is to decide how best to tackle his problem, i.e. how to programme himself. The outcome of his attempts to solve the problem will therefore probably depend on the interaction of several more or less independent computing mechanisms and on the effectiveness of the programming. It is thus very unlikely

that common descriptive functions $f(D, K)$ can be evolved which will describe the overall input/output characteristics of all subjects when they are attempting complex tasks, since the programming, and thus the computing mechanisms called into play and the order in which they are utilized, will vary from one subject to another. The analysis which has been attempted in the foregoing pages is thus applicable only to the computing aspects of human problem solving, and experimental work pertinent to the analysis can only be carried out by using highly structured tasks within which opportunities for differences of individual approach are as completely eliminated as may be possible. It may not be altogether fanciful to regard these computing mechanisms as making up an important part of "Intelligence A," as defined by Hebb (1949), while his "Intelligence B" would seem to result from the subject's gradual acquisition of sets of programmes suitable for bringing them into effective combination.

However this may be, it does seem probable that the investigation of both normal and abnormal cognitive function should take some account of the discussion here attempted, if it is to lead to fruitful results.

CHAPTER 6

Cognitive Abnormalities

R. W. PAYNE¹

I. GENERAL COGNITIVE LEVEL

Introduction

This chapter will attempt to summarize those research findings which deal with abnormalities of cognitive function, and the relationship between cognitive and other abnormalities. One large category of cognitive abnormality will not be dealt with, namely mental deficiency. Mental defectives are traditionally subdivided into the endogenous and the exogenous. The former category is held to be the result of heredity, and is thus more relevant to the discussion of genetically determined abnormalities given elsewhere. The latter disorder is held to be the result of brain damage, and this subject is also dealt with elsewhere.

Before attempting to theorize about cognitive abnormalities, it is useful to have some comprehensive theory about normal cognitive processes. Unfortunately no such theory exists. Furneaux has produced strong arguments against regarding "general intelligence" as a basic scientific concept. He points out that the *g* score derived from any cognitive measure is the result of interactions between a number of more fundamental processes. Similarly he regards Thurstone's "Primary Mental Abilities" or "factors" as principles of classification based on the content of the problem to be solved, but probably complicated by the fact that different basic processes may interact differently for each of these factors. It is not therefore proposed to regard either *g* or the P.M.A. factors as variables fundamental to a scientific analysis of cognition.

Some learning theorists have proposed "models" of problem-solving or cognition. They believe that cognition can be fitted into the general framework of learning theory, and that problem-solving is in essence the occurrence of internal mediating stimulus-response processes, which cannot be observed but only inferred. The postulated "response" provides the internal stimulus for subsequent observable behaviour.

By and large there are two schools of thought. For example, Maltzman (1955) believes that problem-solving is merely internalized "trial and error" learning, the reinforcing agent being the production of an "anticipatory goal response." This hypothetical construct is merely an internalized representation of the rewarding state of affairs which is to follow. In easy problems, the correct internal mediating response has a high habit strength (and probability of occurrence). In difficult problems the correct response has a low habit strength, and the solution of the problem must await the extinction (through lack of reinforcement) of the stronger but incorrect competing responses. (It is difficult to see why the correct response should produce this rewarding "anticipatory goal response." This presupposes an already existing connexion between the "correct" response and the "goal." In other words, it presupposes that the subject has already learned from past experience that this is the correct answer, an assumption for which there is little support in many cases.)

Other theorists (e.g. Maier, 1931*a*, 1931*b*, 1945), while accepting that cognition is the occurrence of some internal mediating process, deny that trial and error learning and reasoning can be identified. Maier (1931*a*) argues that reasoning as distinct from learning, involves a manipulation and reorganization of past experience and can be observed even in the rat. He believes that internal trial and error learning cannot account for the observed results, because the solution is perceived too quickly, and an intermediate stage is lacking (Maier, 1931*b*).

Perhaps the main fault of both types of theory is that they have produced no crucial experiments to decide between them. Neither theory appears capable of producing a precise enough prediction to disprove itself. This sort of theory, then, will be of little help in providing a frame of reference around which to order the considerable mass of data on cognitive abnormalities.

¹ Now Associate Professor of Psychology in Queen's University, Kingston, Ontario.

Guilford (1956) has produced an extremely elaborate analysis of cognition. He also proposes to discard "general intelligence" as a basic concept, and suggests that "intelligence" is much more complex than formerly imagined. He has subdivided problem-solving into various stages which he calls "cognition (discovery)," "production (convergent thinking)," "production (divergent thinking)," "evaluation" and "memory." Within each stage of problem-solving he has isolated numerous "factors" representing the type of material to be reasoned about (e.g. verbal), the type of reasoning required, and so on. This scheme has been evolved with the aid of a large number of factor analyses, this statistical tool being used in each study to test the hypothesis that a certain "mental process" can be identified. Guilford's analysis is not a theory in the sense that it explains the *mechanisms* of problem-solving. It does however provide a possible "cognitive map" with which to explore abnormalities of thinking. Guilford's theory has not been used in the present chapter as a frame of reference. This is mainly because it has never been applied in the study of mental abnormality, and is probably over elaborate for the purpose of classifying those data which exist at present. Nevertheless Guilford's analyses can probably provide some objective support for most of the principles of classification which *have* been adopted.

The frame of reference which will be used in the following discussion of cognitive abnormalities is based on Furneaux's analysis of problem-solving, although several extensions to Furneaux's scheme have been introduced. For the sake of clarity, this scheme is laid out below with a brief definition and description of each heading.

Frame of Reference

GENERAL INTELLECTUAL LEVEL

The majority of cognitive tests yield a score which is regarded as a measure of "general intelligence" or g. It is clear that g is conceived of as some sort of "average" intellectual score, and is usually measured by a single test most representative (factorially) of a wide group of tests administered (usually) without a time limit. While such scores are admittedly useful in predicting certain types of behaviour, as Furneaux demonstrates, they are not measures of fundamental psychological variables. The same g score can be produced by quite different interactions of fundamental variables. For example, a slow thinker who makes few errors and has low persistence might obtain the same g score as a fast thinker who makes many errors, but who has the same persistence. A single g score is not an adequate description of the cognition of the two individuals.

"General intelligence" or "general level" must inevi-

tably be discussed since the bulk of the data in abnormal psychology is derived from such measures. It is clear, however, that any results which relate to general intelligence must remain ambiguous, as they do not tell us what difference in specific intellectual function yielded the observed difference.

VARIABILITY OF PERFORMANCE

It is known that an individual's level of performance on precisely the same reasoning task varies from day to day. Furthermore, there may be important individual differences in the amount of variability that occurs. Variability may partly be a function of the type of test material. Some people might be more variable on problems of some "content" than on others. Variability might in fact interact with any of the other variables to be discussed. The causes of such variability may themselves be numerous and complex, including variations in motivation, general health and so on. Hull (1943) believed that there is an irreducible core of inexplicable and unpredictable variation perhaps due to some property of the nervous system, and following Spearman, used the term "oscillation" to describe it.

CONTENT

Perhaps the first obvious division of cognitive tests is according to their content, or the nature of the data to be thought about. It is possible to differentiate between problems whose data are largely "numerical," "verbal," "spatial" and so on. It is clear that tests of different content do not intercorrelate perfectly, and this may be the main (but probably not the only) reason that relatively specific "factors" of intelligence can be demonstrated (e.g. Thurstone's Primary Mental Abilities). This principle of classification by content, of course, makes no reference to the type of *reasoning* the subject is required to do, nor to the mechanisms and thought processes involved.

TYPE OF PROBLEM

If any collection of cognitive tests is viewed dispassionately, perhaps the most surprising feature is the variety of types of problem the label refers to. Quite different types of reasoning are required for different problems. Some tests require nothing besides *inductive reasoning* (many sorting tests of concept formation are of this sort). Other tests involve straightforward *deductive reasoning* (e.g. some arithmetical problems). A large number of tests require a combination of these two processes for their solution (e.g. the Thurstone letter-series test). Some tests merely require the subject to produce as many curious "ideas" as possible, and Guilford (1956) calls them tests of *originality*. Some tests are nothing more than measures of *perceptual discrimination* (e.g. the

tests which define the United States Employment Service (1955) General Aptitude Test Battery "P" factor). Rather different tests are those which require the subject to imagine what a visual pattern or diagram would look like if rotated (or otherwise altered in its spatial orientation). These are commonly called tests of *spatial reasoning*. Some tests merely assess the subject's *immediate memory span* (e.g. the Wechsler-Bellevue Digit Span subtest), some assess his capacity for *rote learning* (e.g. some subtests of the Babcock Levy (1940) test of "mental efficiency"), and finally there are some which assess nothing more than the long-term capacity for *retention* of items of information (e.g. the Wechsler-Bellevue Information subtest).

What is so surprising is not that these various "cognitive" measures intercorrelate imperfectly, but that they intercorrelate at all. Yet innumerable studies have clearly demonstrated a relationship between all these measures. Many tests of course involve combinations of these different mental operations.

It is obviously quite possible to classify tests in accordance with the type of reasoning required, and while such a principle of classification is not completely independent of the "content" of the problems, it is nearly so. Thus this "variable" may well interact with all the other variables to be discussed.

THOUGHT PROCESSES

The variables so far discussed all refer to methods of classifying the problems to be solved. They do not deal with the thought processes used in their solution. No attempt will be made to elaborate in detail a theory of cognition. However, the following headings all refer to aspects of thought which are known to be involved in solving cognitive tests.

(a) Speed

Furneaux has demonstrated that the speed of returning a *correct* solution to a problem may be one of the most fundamental variables in cognition. This is an important source of individual differences. However, speed may interact with any of the other variables discussed. For example, some people may be quick at solving problems with "verbal" content, but slow at other sorts of material. Speed by itself is only a partial determinant of score in most tests, and its importance will vary from test to test. (Because people tend to "give up" extremely difficult problems rather than devote too much time to them, it can be a determinant of the score even in untimed tests.)

(b) Persistence

A second determinant of the score on many tests is persistence. For most types of problem, the longer the individual is prepared to think about it, the greater

the probability of obtaining a solution. Again this factor can interact with all the other variables. For instance, in an untimed test, persistence can compensate for slowness. Persistence may be partly a function of such variables as the content of the test. It may also be partly a function of "drive."

(c) Error

The tendency to give an incorrect solution in the belief that it is correct, in contradistinction to the "abandonment" of a problem, is another determinant of ultimate performance which is a source of individual differences. Again this variable can interact with the other variables discussed. Error also could partly depend on the "content" and the "type" of the problem.

(d) Distractibility

It is clear that in order to solve a problem, one must give one's attention to it. If the relevant thought processes are interrupted, the solution will be delayed, and the problem might even be abandoned before solution occurs. Individual differences in the ability to concentrate on the task in hand are clearly a factor in determining success. Again this variable can interact with the other variables mentioned.

(e) Memory Span

At first sight it is difficult to see why tests of immediate memory span (e.g. the Wechsler-Bellevue Digit Span Test) correlate so highly with other cognitive measures (Wechsler, 1944). On reflection this is perhaps not so unexpected. In order to solve any problem it is necessary to hold the test instructions in mind. People whose memory span is small will be handicapped if they forget part of the instructions. In orally administered tests, the data of the problem itself must be held in mind (e.g. in the Wechsler Arithmetic test) while possible solutions are considered. If any item is forgotten, a solution may become impossible. Even in written problems, where the test data can be referred back to, such checking could result in slowness which itself could lead to the abandonment of the item. Memory span is clearly relevant to "spatial" items (e.g. the Wechsler Block Design test where the subject must, at least temporarily, "retain" in his mind the design he is trying to build while he arranges the blocks).

(f) Learning

Individual differences in rote-learning capacity are clearly correlated with other cognitive measures (Ingham, 1949, 1952). This is probably because, for problems where the subject's immediate memory span is too small for all the relevant data to be retained on one repetition, some of the test data must be memorized before the process of finding a solution can begin.

Also in many cognitive problems (e.g. the Wechsler Block Design test) the subject must *learn* from the easier items what methods of manipulation are fruitful in order to solve the later more difficult items. This learning proceeds largely through trial and error, but individuals who are poor at learning will tend to get poor scores.

(g) Retention

Many cognitive problems depend for their solution on the utilization of items of information acquired in the past. It is obvious that arithmetic problems become extremely difficult if one has forgotten one's tables. In other words, one often brings to a problem certain possible solutions or partial solutions which one has learned in the past. If retention is poor, performance will tend to be impaired. Some test items of course consist in nothing more than asking the subject to recall solutions to problems he has learned in the past (e.g. many "comprehension" test items), or pieces of information he has learned by rote in the past (e.g. "information" test items).

(h) Drive

Since learning and cognition cannot be separated completely, drive will be a variable relevant to problem-solving if only because it affects rote learning. In addition, however, it probably affects persistence, and may also considerably influence the *speed* with which solutions occur (cf. Furneaux).

(i) Rigidity

If rigidity is the tendency to continue to pursue one line of thought after it ceases to produce correct answers, and if there are individual differences in rigidity, this variable will also directly affect problem-solving ability.

(j) Concept Formation

The "concept" is the manipulandum of thought. It is obvious that in any problem expressed verbally, if one person uses a word to denote one concept, and another person uses the same word to denote a different concept, even though both use identical reasoning processes, each will reach a different solution. An understanding of concept formation and the mechanisms on which it is based is clearly crucial to an understanding of thinking.

These then, are some of the variables which determine performance on cognitive tests. It is proposed to discuss *abnormalities* of cognitive function (and their associated abnormalities) under these general headings.

Intellectual Level during Mental Illness

The impairment of intellectual functioning in individuals who were once normal has long been

regarded as a cardinal feature of insanity. Popular terms such as *lunatic*, *crazy*, and *insane* and medical terms such as *dementia praecox* suggest that intellectual deficit is the most striking feature of some types of illness. In the last century of course, many cases of dementia were undoubtedly due to organic diseases of the brain which have since been identified (e.g. G.P.I. resulting from syphilis of the central nervous system). Nevertheless most psychoses are still regarded as "functional" and no clear-cut causes have been demonstrated.

In spite of this, there has been an extremely unfortunate tendency for psychologists to regard psychiatric diagnostic labels as of fundamental importance to a scientific analysis of mental abnormality. Countless studies attempt to find objective correlates of these labels. Thus, instead of investigating, for example, the nature and causes of "slowness of problem-solving," a psychological variable which can be accurately defined and measured, and clearly related to other psychological variables, psychologists have concerned themselves with investigating the performance on batteries of tests of individuals whom psychiatrists have labelled "schizophrenic." They have never enquired closely into the meaning of the term schizophrenic, nor have they apparently been concerned to discover whether or not schizophrenia *can* be defined and detected accurately enough to make it a fundamental variable to which everything else must be related.

It is clear from Chapter I (H. J. Eysenck) that at least as far as the psychoses are concerned, psychiatric diagnostic categories do *not* have the status of scientific concepts, and therefore should *not* be regarded as in any way basic to an analysis of cognitive abnormality. However, the bulk of the literature relates test results to psychiatric labels, and not to specific symptoms rated independently by unbiased observers, nor to other unambiguous data about the patients. Therefore it will be difficult to interpret most of the studies. Even if some correlations with psychiatric labels *are* observed, the reasons for these will not be clear. The behavioural correlates of specific cognitive dysfunctions can only be speculated about from the data so far available in the literature.

One of the earliest studies investigating the general intellectual level of mental patients on a standard intelligence test was that of Wells and Kelley (1920). They administered the Binet test to one hundred and one psychotics and found a slightly lower than normal I.Q. The group included both schizophrenics and manic-depressives. Schott (1931) reports the results of a larger survey, also using the Binet test. He tested four hundred and fifty mental patients of all types, and reports "a moderately normal type of distribution skewed slightly toward the lower end

of the scale." The median I.Q. was 92.4, the bottom quartile was 75.1 and the top quartile 103.87.

The earlier literature on general intelligence in mental patients has been well reviewed by Brody (1941) and Hunt and Cofer (1944). The latter authors point out that almost all the studies done up to that time used such tests as the Point-Scale or the Stanford-Binet, which were standardized on children. "This introduced age as an uncontrolled variable . . ." (Hunt and Cofer, p. 973, 1944). Therefore they regard their conclusions as tentative. Since then, the

Eysenck, 1947; Fey, 1951; Garfield, 1948 and 1949; Gilhooly, 1950; Gilliland, Wittman and Goldman, 1943; Hall, 1938; Harper, 1950a; Kogan, 1950; Lewinski, 1945a, 1945b and 1947; Olch, 1948; Rabin, 1941, 1944a, 1944b; Rapaport, Gill and Schafer, 1945; Rogers, 1951; Stotsky, 1952; Warner, 1950; and Webb and De Haan, 1951.)

This table needs considerable amplification and qualification. It is based almost entirely on the Wechsler-Bellevue scale, as this test is adequately standardized for age, and the I.Q. scores at each age

FIG. 6.1. DISTRIBUTION OF INTELLIGENCE-TEST SCORES OF 5,000 NEUROTIC AND 3,665 NORMAL SOLDIERS

(From H. J. Eysenck, "Dimensions of Personality")

use of the Wechsler-Bellevue Scale (Wechsler, 1944) has become widespread, and many more data are available. Table VI.1 is based on a collection and

TABLE VI.1
INTELLIGENCE QUOTIENTS IN ABNORMAL GROUPS

(Wechsler-Bellevue except where noted)

Category	Mean I.Q.	No. of cases
Civilian neurotics	105.01	987 (includes 145 on Matrices)
Neurotics (Army Service breakdowns)	93	5,000 (all on Matrices)
Epileptics	107.51	425
Schizophrenics	96.08	1,284
Affective psychoses	94.87	65
Paranoid condition	118.3	7

combination of some of the more recently published data on the I.Q. levels to be found in various abnormal groups. (The table makes use of the data reported by Altus and Clark, 1949; Bannatyne, 1953; Carp, 1950; Cohen, 1950 and 1952a; Collins, 1951; Dana, 1957;

level are comparable (having a mean of 100 and a standard deviation of 15). However, in some cases additional I.Q. results obtained from Raven's Progressive Matrices test (Raven, 1950) were added. This was thought permissible since the Matrices test is also well standardized for age, and in the case of all the data included, the I.Q. quoted has a mean of 100 and a standard deviation of 15 for each age-group.

Perhaps the most interesting mean I.Q.s are those derived from individuals diagnosed neurotic. The civilian neurotic group includes only cases of breakdown in civilian life, although in many cases the subjects were war veterans (and indeed treated in "V.A." hospitals). The army service breakdown neurotic sample is one reported by Eysenck (1947), and consists of soldiers from the British Army who broke down during service in the 1939-45 war. The mean I.Q. level of the two groups is quite different. Eysenck gives the entire I.Q. distribution of his service breakdown neurotic group (based on the Matrices test). This is shown in Fig. 6.1.

In the same study, Eysenck (1947) compares the level of intelligence of the neurotic soldiers with the level of intelligence found in a group of matched soldiers who did not break down. The neurotic soldiers were significantly duller (average Matrix score for neurotics = 39.36 ± 9.90 ; for normals,

average = 42.24 ± 9.77 , C.R. = 14), although they had a higher proportion of extreme I.Q.s. He suggested that there might be a tendency for duller individuals to find army life more stressful and thus to break down more easily. He also suggested that the reverse might be true in civilian life, namely that in western societies the brighter people might find life more stressful and frustrating and thus tend to develop neurotic breakdowns more readily.

The mean I.Q. shown in Table VI.1 for civilian neurotics seems to bear out this suggestion. It was not possible to calculate a combined standard deviation from the entire nine hundred and eighty-seven civilian neurotic cases. However, it could be calculated from five hundred and eighty-eight of these cases. (This smaller group of five hundred and eighty-eight, all of whom had the Wechsler-Bellevue test, had a mean I.Q. of 105.27, which was very close to the mean of the entire group.) The standard deviation of this group was only 13.61. In other words, civilian neurotics are both brighter and more homogeneous than the normal population (as estimated from Wechsler's norms). Put in another way, these figures suggest that there are just as many very bright neurotic patients as very bright normal people, but whereas about 10 per cent of normal people have an I.Q. of 81 or lower, only about $3\frac{3}{4}$ per cent of the civilian neurotic population is as dull as this.

The mean I.Q. for epileptics was included in the table because it was once thought that epilepsy produced a progressive intellectual deterioration. The mean epileptic I.Q. of 107.51 given in Table VI.1 is perhaps misleading, as four hundred of the four hundred and twenty-five cases are derived from a single study by Collins (1951). She points out that the higher than average I.Q. of her group might be due to the fact that most were private patients from a relatively high socio-economic group. Collins's study suggests clearly that: "There is little evidence of deterioration except in organic cases." The average I.Q. for "essential epileptics" in this study was 111.20, for "traumatic epileptics" only 98.95, a difference significant at the 1 per cent level. Similar findings are reported by Winfield (1951) on sixty cases using the Wechsler, Thurstone's P.M.A. test, and the Matrices. These results are consistent with the bulk of the evidence in the literature according to a recent review by Jones (1953). It seems clear that epileptic seizures as such do *not* result in a general intellectual deterioration, although brain damage associated with epilepsy (or with any other set of symptoms) can in many cases produce a general intellectual deficit.

The mean I.Q. of 96.08 for a group of 1,284 schizophrenics is perhaps surprisingly high, as this disease is regarded, at least in many cases, as a dementing condition. It was not possible to calculate a standard

deviation from all the cases. However, this was done for a smaller group of eight hundred and twenty-five cases (whose mean Wechsler I.Q. was 96.45, very close to the mean of the whole group). The standard deviation was 16.69. Thus schizophrenics would appear to be both duller and more heterogeneous than the general population. For example, while only 10 per cent of the general population have an I.Q. of 81 or lower, $17\frac{1}{2}$ per cent of the schizophrenic population are as dull as this, or duller, according to these data. On the other hand, $8\frac{1}{2}$ per cent of schizophrenics have an I.Q. of 119 or higher, while 10 per cent of normals do as well or better than this. It is tempting to conclude that schizophrenia is not a single "illness" but a name used to cover a considerable variety of conditions, some of which have associated intellectual disturbances and some of which have not.

One important additional factor must be considered in relation to the schizophrenic data. While the neurotic group is probably reasonably representative of the general neurotic population, this is almost certainly not the case for the schizophrenic group. Fourteen of the studies from which the schizophrenic data are derived report the mean age of the schizophrenic group they tested. Except for two groups of paranoid schizophrenics (whose mean ages were 36.4 and 43.8) the highest mean age reported was 33.7 and the lowest 26.9. An examination of the age standard deviations (where given) reinforces the conclusion that almost *all* the schizophrenic data are derived from the age-group 20 to 40. Almost certainly there are large numbers of chronic schizophrenic patients over 40, resident in mental hospitals, and if it is true that at least a proportion of schizophrenics dement progressively, their scores must be lower than those reported, so that the present mean is probably unduly high. Probably a factor which introduces an enormous bias into this sample is that of testability. Many psychotic patients are so uncooperative or unresponsive that they are too difficult to test with the Wechsler-Bellevue, and the scores of this group, which may well be large, are clearly not represented. These patients may well include the more intellectually impaired.

That it is possible to select schizophrenic groups which have quite a low general intelligence when tested is clear from a number of studies. For example, Mainord (1953) tested a group of twenty-two schizophrenics judged to have deteriorated, and these obtained a mean I.Q. of only 84.5 on the Wechsler-Bellevue. Similarly Malamud and Palmer (1938) report a group of one hundred deteriorated schizophrenics who obtained a mean mental age of only 126.3 months (S.D. 14.4) on the Stanford-Binet.

The data available for affective psychosis are surprisingly few. The mean given in Table VI.1 is based

on only sixty-five cases, and the studies on which it is based fail to provide enough information to make it possible to calculate a standard deviation that would be in any way representative. There is no real evidence that affective psychoses differ in tested I.Q. from schizophrenics in the older studies such as that of Barnes (1924), and the data reviewed by Hunt and Cofer (1944) generally support this conclusion.

Little can be said about the category of paranoid condition on the basis of the seven cases reported by Rapaport, Gill and Shafer (1945). Lack of contemporary data suggests that the use of this label has become out of date.

General intelligence has been related to two other large groups of behavioural abnormality. The first is delinquency. It is fairly well established that convicted delinquents, both adult and child, tend to have a mean I.Q. significantly below average. Taylor (1938) assessing 10,000 male adolescent prisoners (aged 16 to 22) on the Columbia group test, found a distribution of I.Q. skewed towards the lower end of the scale. Of the group three hundred and twenty-two were in fact illiterate. Mann and Mann (1939) report the same type of distribution of Binet test I.Q.s obtained from 1,061 delinquent boys and six hundred and seventy delinquent girls in their teens. They report a mean I.Q. for boys of 84.88 and for girls of 83.77. A similarly shaped distribution with a rather higher mean is reported for adults by Shakow and Millard (1935). These studies suggest that individuals of low intelligence are much more likely to get into trouble with the law. Whether low intelligence led them into crime, or merely caused them to get caught it is not possible to say.

Addiction to drugs is another category of abnormality which some earlier studies, often of rather few cases, related to low intelligence. For example, Hall (1938) tested thirty-seven female drug addicts, after withdrawal, on the Army Alpha, and found a mean I.Q. of 96.2 (S.D. 16.5). However, a fairly large study by Brown and Partington (1942) does not support this. They gave the Wechsler-Bellevue to three hundred and seventy-one narcotic drug addicts and found that "drug addicts range in intelligence from defective to very superior, with the largest percentages falling into the average and bright-normal classifications." However the addict group showed "a lower percentage of cases in defective and in the very superior intelligence classifications as compared with Wechsler's normal group."

The functional psychiatric diagnostic categories so far considered have been very broad. The data presented in Table VI.1 can to some extent be broken down. The results for the civilian neurotics are shown in Table VI.2.

TABLE VI.2
INTELLIGENCE QUOTIENTS IN SUBGROUPS
OF CIVILIAN NEUROTICS
(Wechsler-Bellevue except where noted)

Category	Mean I.Q.	No. of cases
Neurotic (not specified)	103.63	676
Mixed neurosis	107.23	72 (includes 63 on Matrices)
Hysteric	106.11	43 (includes 25 on Matrices)
Psychopath	100.64	33 (includes 21 on Matrices)
Obsessive-compulsive	114.16	27 (includes 11 on Matrices)
Anxiety neurosis	109.65	120 (includes 25 on Matrices)
Neurotic depression	109.28	72 (includes 63 on Matrices)
Total introverted neurotics	110.36	163 (includes 36 on Matrices)
Total extraverted neurotics	103.74	76 (includes 46 on Matrices)

Unfortunately most of the cases reported in the literature are not described in detail, or given any label other than neurotic. The cases which are subdivided have a higher overall mean intelligence, although this may be purely accidental. The main finding suggested by the table is that the neurotic groups classified by Eysenck as introverted (obsessive-compulsives, anxiety neurotics and neurotic depressives) have a higher mean I.Q. than those classified as extraverted (hysterics and psychopaths). Precisely the same observation was made by Eysenck (1945) on the 5,000 wartime army service breakdown neurotics. His results are presented in Fig. 6.2.

The mean raw Matrices score for the dysthymic neurotic group was 40.12 (S.D. 10.10). The mean score for the hysteric group was 37.12 (S.D. 12.08). The difference was highly significant (C.R. = 4.6). Bradford (1941) similarly reports a high incidence of hysterics among soldiers with very low test scores.

This apparently reliable finding is difficult to explain. Certainly extraverted neurotics are less common in mental hospitals than introverted neurotics. It is conceivable that extraverts find the same degree of neuroticism (and the symptoms resultant from it) less troublesome than introverts. Therefore they tend not to seek treatment. *Belle indifférence* is traditionally

regarded as accompanying hysterical physical symptoms, and it is often claimed that these symptoms are unconsciously motivated, actually serving the purpose of making life more pleasant for the patient. Anxiety and obsessional symptoms on the other hand are seldom pleasant. It is conceivable that those hysterics who do become patients are more severely neurotic than their dysthymic counterparts. If we accept that a severe degree of neuroticism can produce some

At first sight, this breakdown is rather curious. The large bulk of cases are not given any label other than schizophrenic, and the two brightest groups are "schizophrenics" and "mixed schizophrenics." It is possible that many of these cases could have been labelled "early schizophrenics" or "acute schizophrenics." In other words, it is possible that these cases have been ill for a relatively short period of time, and do not present such severe or clear-cut symptoms.

FIG. 6.2. DISTRIBUTION OF INTELLIGENCE-TEST SCORES OF 904 DYSTHYMICS AND 474 HYSTERIC
(From H. J. Eysenck, "Dimensions of Personality")

intellectual impairment, the results could be explained. This suggestion, however, is extremely tentative and there is no other evidence to support it.

The breakdown of the schizophrenic group is given in Table VI.3.

TABLE VI.3
INTELLIGENCE QUOTIENTS IN SUBGROUPS
OF SCHIZOPHRENIA
(Wechsler-Bellevue I.Q.)

Category	Mean I.Q.	No. of cases
Schizophrenic (not further specified)	97.53	928
Mixed schizophrenics	99.61	72
Paranoid schizophrenics	94.84	166
Simple schizophrenics	88.23	44
Catatonic schizophrenics	82.80	45
Hebephrenic schizophrenics	80.60	29

For this reason they have not been further classified. If this group tends to be less severely ill, and contains many early cases of intellectual impairment which is progressive, it is not surprising that the group has the highest I.Q.

Where the patients have been further classified, it is interesting to note that those labelled paranoid schizophrenic are substantially brighter. This is even more striking since the average age of the "paranoid" subgroup is approximately 40, probably considerably older than the other subgroups (age data are unfortunately scanty for the other subgroups). In any event the paranoid schizophrenics have probably had at least as long to dement as the other subgroups. The data suggest, then, that schizophrenic patients with low levels of I.Q. are more likely to be labelled "catatonic" or "hebephrenic," and that those labelled "simple" are intermediate. Whether this is because the specific symptoms, to which these labels refer, are related to more severe intellectual impairment, or

because these patients have always been dull, it is not possible to say from these figures. Nevertheless, the former explanation would probably be more generally accepted.

The breakdown of the affective psychoses is presented in Table VI.4.

TABLE VI.4
INTELLIGENCE QUOTIENTS IN SUBGROUPS
OF AFFECTIVE PSYCHOSIS
(Wechsler-Bellevue I.Q.)

Category	Mean I.Q.	No. of cases
Manic-depressive (depressed state)	103.3	18
Depressive	91.0	8
Manic	90.0	32
Involucional depression	99.9	7

Were the numbers not so small, this table would suggest that involutional depressives do not apparently suffer from any impairment, while depressives and manics are roughly comparable in level to schizophrenics. It is clear, however, that firm conclusions cannot be drawn. The label "manic-depressive" traditionally refers to patients who have periods of mania and periods of depression alternating (just as the single labels "depressive" and "manic" imply recurring conditions of this sort *without* alternations between the two extremes). Modern usage, however, at least among psychologists, has probably become imprecise. All the manic-depressives reported were tested in a depressed phase, and it is possible that some psychologists use the term manic-depressive to include individuals with recurring depression who never show manic attacks. It would probably not be correct to conclude from this table that the cyclic disorders show no evidence of mental impairment.

DIRECT EVIDENCE FOR GENERAL IMPAIRMENT WITH MENTAL ILLNESS

All the results so far discussed are ambiguous in the extreme. No evidence has been presented to show that the intelligence of these patients (the psychotics especially) was not always at the same level. In other words, is psychosis a condition tending to occur more frequently among the dull, but itself producing no intellectual deficit, or do psychotic illnesses tend to produce intellectual impairment in people who were formerly normal? Few good studies have been carried out on this subject because of the obvious difficulty of obtaining and testing people who will later develop mental illnesses.

Probably the earliest study is one by Gardner

(1931) who examined the school records of one hundred adult schizophrenic patients and one hundred manic-depressive psychotics. He concluded that they were generally worse at school than their colleagues, but had more specific ability for art and music. No statistical analysis was performed and the study is not very informative. The same author later reported a different type of study (Gardner, 1940). A total of 3,500 normal children in Massachusetts was studied

FIG. 6.3. DISTRIBUTION OF A.G.C.T. STANDARD SCORES FOR 510 PSYCHIATRIC IN-PATIENTS (SOLID) AND CONTROL DISTRIBUTION BASED ON DATA FOR 290,163 FIFTH SERVICE COMMAND INDUCTEES (BROKEN)

(From C. F. Mason, "Pre-illness Intelligence of Mental Hospital Patients")

year by year starting in 1922. Each year their intelligence was tested. By 1940, twenty-two had been admitted to a mental hospital. Their pre-illness I.Q. test scores were all below average, but since the group contained only six psychotics, few conclusions can be drawn.

A more satisfactory study is reported by Birren (1944). From the files of a child guidance clinic, the records were obtained of a group of thirty-eight children who had later become psychotic (schizophrenic, constitutional or organic, or miscellaneous, i.e. neurotic or psychotic reaction). He also examined fifty-three control cases who had not later become psychotic. The study suggested that "pre-psychotic cases as a group do not differ in intelligence from the general population studied by the Bureau of Child Study."

The only direct proof of intellectual deterioration with psychosis with which we are familiar is a study by Rappaport and Webb (1950). They found ten schizophrenic patients who had taken an I.Q. test in high school before they became ill. Each subject was given the *same* test again. The mean former I.Q. (in high school) was 97.60, while the mean present I.Q. (when psychotic) on the same tests, was only 63.90, a difference significant at the 1 per cent level.

The largest study of pre-illness I.Q. is reported by Mason (1956), who obtained a sample of five hundred and ten inductees of World War II, all of whom, as veterans, later broke down with some functional psychiatric illness. All had been given the American Army General Classification Test on being accepted for service. The pre-illness I.Q. scores of this group were compared with the scores obtained by a carefully matched control group consisting of 290,163 Fifth Service Command Inductees. Fig. 6.3 compares the pre-illness I.Q.s of the inductees, who later broke down, with the normal controls.

There is *no* statistically significant difference between the two distributions. At first sight these results would appear to support the contention that the below average I.Q. scores among psychotics are entirely a result of their illness. Mason, however, also gives the following table relating *type* of psychiatric illness to pre-illness level by comparing each group with the normal controls—

TABLE VI.5
DIFFERENCES IN PRE-ILLNESS I.Q. BETWEEN
CONTROLS AND DIFFERENT DIAGNOSTIC
GROUPS
(After Mason)

Group	N	d.f.	Chi square	p	Trend
All Patients . . .	510 ¹	16	22.32	0.14	
All schizophrenics .	368	16	32.60	0.02	low scores
Paranoid . . .	66	3	3.10	0.39	
Catatonic . . .	126	7	10.61	0.19	
Hebephrenic . .	122	7	17.55	0.02	
Simple . . .	33	2	12.46	0.002	
Other . . .	21	1	4.77	0.05	
Non schizophrenics .	188	12	7.78	0.79	high scores
Alcoholism . . .	29	1	0.61	0.90	
Neurosis . . .	79	5	1.93	0.20	
Manic-depressive .	25	1	17.65	0.001	
Character disorder	55	3	4.21	0.25	

¹ This total is reproduced from the original article. The author does not explain how it is related to the subtotals below.

Unfortunately no I.Q. figures are given. Nevertheless the trends are interesting. It would appear that the "schizophrenics" as a group were below average in intelligence even before they became ill, while those labelled "manic-depressive" were above average. Both findings are consistent with the data in Tables VI.3 and VI.4. The finding that the pre-illness intelligence of hebephrenic schizophrenics is considerably below average is also consistent with Table VI.3. A lack in Mason's data, is any reference to depressives or manics, two groups whose I.Q. during illness is apparently well below average.

The conclusions which can be drawn from this study are limited, since the author did not retest the subjects on the same scales, and thus provide a direct measure of the amount of deterioration, if any, which had occurred. The finding, however, that the pre-illness I.Q. of schizophrenics is below average suggests that the amount of deterioration presumed to have occurred in many schizophrenic groups may have been overestimated. There is also a strong possibility that the label hebephrenic schizophrenic becomes attached to patients who have *always* been dull, just as the label paranoid schizophrenic may become attached to patients who have always been of about average intelligence.

Another method of demonstrating that psychosis produces impairment is by testing patients before and after recovery; but very few studies of this sort appear to have been made. Graham (1940) tested thirty-three schizophrenic patients on the Binet scale before and after insulin shock therapy. There was no significant difference in test score. We cannot, however, necessarily conclude that the insulin "cured" the patients, nor does the author claim this.

Davidson (1939) gave the Binet test to twenty-eight manic-depressive psychotics, and retested the same patients later. Eighteen had improved clinically, and in every case the Binet score improved. Two were judged worse by the doctors, and their Binet scores had declined. Davidson also tested and retested eighteen schizophrenics and the change in Binet score is reported as coinciding with the change in clinical status. In a second study, the same author tested twenty-five psychotics on the Matrices, and retested them later. Again the change in score is reported as coinciding with the change in clinical status.

Carp (1952) tested forty-two schizophrenic patients on the Wechsler-Bellevue before and after insulin therapy. There was a mean Wechsler I.Q. improvement of 4.7 points, but no control group was tested.

Callagan (1952) tested twenty-five depressive patients before treatment, one week after a course of E.C.T., and again five weeks after E.C.T., on a battery of tests. General intelligence was measured by five Wechsler-Bellevue subtests, both verbal and performance. A control group of twenty-five depressives who had had no E.C.T. was retested after similar intervals. While general intelligence improved after E.C.T., there was no significant difference between the control and experimental group. There was, however, a significant relationship between I.Q. improvement and clinical improvement rated by psychiatrists in *both* groups, so that the lack of significant differentiation in final I.Q. between the groups may partly have been because many of the untreated cases had also recovered considerably.

Another treatment claimed at least temporarily to

improve schizophrenics is the administration of sodium amytal. Several studies have investigated whether or not amytal also improves the general intellectual level of the schizophrenic. A fairly early study by Layman (1940) produced apparently quite striking results. Twenty schizophrenics were given the Binet and a form-board test before, during and after amytal. The Binet test results were much better for patients under amytal, but dropped back to their initial level on the third administration after the drug had been withdrawn. Similarly Mainord (1953) tested twenty-two deteriorated schizophrenics (who also had abnormal EEG records) before, during and after amytal, on the Wechsler-Bellevue. Their pre-amytal mean I.Q. was 84.5, their mean amytal I.Q., 100.6; and their post-amytal mean I.Q. only 86.4, a highly significant improvement being shown while the drug was being administered. A control group of eighteen non-deteriorated schizophrenics retested without the drug showed an average increase of only one I.Q. point.

Senf, Huston and Cohen (1955), however, obtained different results. They tested twenty-four chronic schizophrenics, twenty-two early schizophrenics, twenty-one depressives and twenty-one neurotics on a number of tests before and during amytal. General intelligence as estimated from three Wechsler Verbal Scale subtests did not alter significantly with amytal in any of the groups. Two recent studies by Ogilvie (1954) and Broadhurst (1957) criticize earlier work for failing to control several variables. In particular, a control group tested with a *placebo* was lacking in the earlier studies. Using the Nufferno test as a measure of general level, neither Ogilvie nor Broadhurst found changes in the general level of schizophrenics which they could attribute to amytal, in two large and extremely well controlled experiments. Both, however, observed fairly large improvements with practice. These studies suggest that the earlier results of Layman and Mainord *might* have been the result of the suggestion implicit in the administration of this drug. However, this alternative explanation is no less startling than the original observations.

One observation that is apparently uncontradicted, is that, by and large, a higher I.Q. score while ill is a better prognosis than a lower one, at least among schizophrenics. Carp (1950) investigated the response of forty-two schizophrenics to insulin treatment. Twenty-six were unimproved, and sixteen were improved. None of the improved group had a pre-treatment Wechsler I.Q. below 95, while fourteen of the unimproved group were lower than this. Stotsky (1952) gave the Wechsler to eighty-eight schizophrenics. After six months, forty-four had remitted and gone home, while forty-four were still in hospital. The remitted group had a mean I.Q. of 107.5 (S.D. 12.7), the unremitted group had a mean I.Q. of only 101.6

(S.D. 12.4), a difference significant at the 2 per cent level. A smaller group of twenty-eight schizophrenics who had remitted after only three months was compared with a group of twenty-eight who were still ill after three months. Again the remitted groups had obtained a mean I.Q. before recovery of 104.1 (S.D. 12.7), the unremitted group had a mean I.Q. of only 97.7 (S.D. 13.0), a difference significant at the 5 per cent level. There was a point-biserial correlation between I.Q. and remission of 0.21 for the first group and 0.24 for the second. These studies might suggest that the less seriously ill psychotic patients have less general intellectual impairment, and tend to recover quicker, although this is merely an unsupported inference.

The only study which gives direct evidence for progressive general deterioration with psychosis is one by Trapp and James (1937). Out of a large group of hospitalized schizophrenics, the authors found forty-one who had been given the Binet test within a week or two of admission, and who had remained in hospital without any remission. The length of this unbroken stay varied from four months to thirteen years. They were all retested on the Binet. If schizophrenia tends to produce a progressive deterioration, all these subjects should have become worse. Furthermore there should be a correlation between the length of the unbroken illness and the amount of deterioration. The authors do not calculate these figures, but fortunately they publish all the raw data, so that they can be worked out. The average Binet I.Q. for the whole group on admission was 82.8. The average retest I.Q. for the group was 75.2, representing a mean decline of 7.6 I.Q. points. The correlation between length of illness and drop in I.Q. for the whole group is 0.39. Both values are as predicted, and suggest that the longer the illness continues, the greater the I.Q. drop.

The authors also subdivide their cases according to type of schizophrenia. There were nineteen cases of paranoid schizophrenia whose mean age on admission was 32.1. Their mean length of illness was three years eight months, their mean admission I.Q. was 88.79, and their mean retest I.Q. 86.47, representing an average decline of only 3.32 I.Q. points. The paranoid group, as is usually the case, had the highest I.Q. on admission, and showed by far the smallest decline in I.Q. Nevertheless there was a correlation of 0.61 between length of illness and I.Q. drop. Since the mean I.Q. drop is small, this figure implies that the short stay cases actually improved their score (perhaps through practice), while the long stay cases were those whose I.Q. declined.

There were seven cases of simple schizophrenia, and, as is usual, these had an intermediate mean admission I.Q. of 79.71. Their mean admission age was 28.7,

and their mean length of illness four years, seven months. Their mean retest I.Q. was 67.14, representing an average decline of 12.57 I.Q. points. The correlation between I.Q. decline and length of illness for this group was 0.57. Again, those who are ill longest, show the greatest decrease in score.

There were eleven cases of hebephrenic schizophrenia, and as is usual, these, along with the catatonics, had the lowest admission I.Q. The mean age of the hebephrenics on admission was 27.3 years, their mean length of illness four years, four months. Their mean admission I.Q. was 76.91, their mean retest I.Q. 63.36, representing an average decline of 13.55 I.Q. points. The correlation between I.Q. decline and length of illness for this group is only 0.03 (in the expected direction), probably because they were all ill a similar length of time and thus show no variation in length of illness.

The four catatonic cases had a mean age on admission of 28.5. Their mean length of illness was two years, ten months, their mean admission I.Q. 75.75 and their mean retest I.Q. 68.25. They show an average decline of 7.50 I.Q. points. The correlation between length of illness and I.Q. drop in this group is 0.48.

This study, then, suggests clearly that a schizophrenic illness without remission tends to produce a deterioration of general level which is progressive. The longer the illness, the more severe the deterioration tends to be. The one exception is that those diagnosed paranoid schizophrenic have a much higher initial I.Q., and while their deterioration also is a function of the length of their illness, it is much slower.

We can conclude from these studies that psychosis probably produces a general intellectual impairment, which deteriorates as psychotics get worse, and improves with recovery. However, direct and unequivocal studies are few.

INDIRECT STUDIES OF GENERAL INTELLECTUAL DETERIORATION

While there are few studies which give direct measures of general level before, during and after psychosis, there are a large number of studies which make use of indirect methods of estimating general intellectual deterioration. The main formal tests of general deterioration are the Babcock-Levy test for the measurement of efficiency of mental functioning (Babcock and Levy, 1940), the Shipley-Hartford test of deterioration (Shipley, 1940), the Hunt-Minnesota test for organic brain damage (Hunt, 1943) and the Wechsler-Bellevue Deterioration Index (Wechsler, 1944). All these tests except the Wechsler make use of the same principle. It is a well-known fact that vocabulary tests in normal people have a high correla-

tion with other tests of general intelligence (Wechsler, 1944). An impressive list of studies (Babcock, 1930, 1933, 1941a; Wells and Kelley, 1920; Altman and Shakow, 1937; Malamud and Palmer, 1938; Davidson, 1938, 1939; Simmins, 1933; Harbinson, 1937; Lidz, Gay and Tietze, 1942; Rabin, 1944; Klehr, 1949; Hunt and French, 1949; Hall, 1951; Rapaport *et al.*, 1945; Wittman, 1933; Schwarz, 1932) suggest that, when normal and psychotic (or brain-damaged) groups are compared on a variety of tests, the test yielding the *smallest* mean difference is a vocabulary test. Usually the groups do not differ significantly in vocabulary score. The implication then is that vocabulary is the ability least affected by mental illness and deterioration. Thus the present vocabulary level of a psychotic subject will be a good measure of his pre-illness level of general intelligence. If the subject is also given a test of his *present* level of general intelligence, the discrepancy between the g score and the vocabulary score will provide a neat indirect measure of the amount of deterioration which has occurred. Babcock was the first psychologist to base a formal test of deterioration on this principle (Babcock, 1930, 1933, 1941a, 1941b).

While the general method would seem to have considerable "face" validity, it is obviously necessary to demonstrate that it works.¹ This would appear to be a simple matter. A group of patients could be given a good test of general intelligence on admission, and could then be retested after a period of time on the same test, and also given a test of deterioration. There should be a high correlation between the amount of deterioration demonstrated on retest, and the indirect deterioration score. Yet *none* of the common tests of deterioration mentioned have ever been validated in this way. The authors and subsequent investigators have been content to repeat the initial observation over and over again, i.e. that there is a larger discrepancy between g tests and vocabulary tests among psychotics (or organics) than exists among normals. Because of this lack of direct validation, data derived from these tests are less than conclusive.

The use of such tests in research has been criticized frequently (e.g. Solomon, 1939; Gerstein, 1949; Lewinski, 1948; Shapiro and Nelson, 1955; and Yacorzynski, 1941). Yacorzynski's (1941) main point is that vocabulary cannot be used as a measure of

¹ Crown (1949) reports the only study in which subjects known to have deteriorated organically were tested in this condition and actually retested on recovery. Four patients with myxoedema were tested while ill on the Mill Hill Vocabulary, the Progressive Matrices and the Shipley Hartford test. They were retested on recovery after treatment. There was a striking improvement on all the test scores. However their vocabulary scores improved just as much as the other scores. This study of course proves nothing about deterioration in functional disorders, but the same indirect measures have been widely used with organic cases.

pre-illness intelligence because it *does* tend to deteriorate with illness. He suggested that this could be demonstrated clearly if vocabulary tests were scored more accurately. That is, instead of scoring a definition correct or incorrect it should be rated for level of acceptability.

Capps (1939) and Shapiro and Nelson (1955)¹ found evidence that vocabulary is not unaffected by deterioration. Chodorkoff and Mussen (1952) administered a specially designed multiple-choice vocabulary test to fifty normals and fifty schizophrenics who were also given the Shipley-Hartford test. The schizophrenics selected a significantly greater number of inferior definitions (less "abstract," more "specific" and more "illustrative"). There was also a significant correlation between the Shipley-Hartford Conceptual Quotient and the type of definition chosen, the more "deteriorated" choosing the less "abstract" type of definition.

Harrington and Ehrmann (1954) gave the Wechsler-Bellevue Vocabulary test to twenty normals and twenty schizophrenics matched for age, sex and I.Q. Scored in the usual way, vocabulary did not differentiate the groups. However, the schizophrenics produced significantly more "concrete" responses as rated. Nevertheless, when both groups were given a special multiple-choice vocabulary test, there was *no* significant tendency for schizophrenics to select more concrete or more unsatisfactory answers.

Ackelsberg (1944) tested fifty senile patients classified by interview as "little deteriorated," "mildly deteriorated" and "marked deterioration." All were given a synonyms test, an antonyms test and a categorization test of classifying species words under the relevant genus word. They also had tests of word fluency and a test of homographs (giving as many meanings as possible to a word). *All* the tests differentiated the groups and the author concluded that all aspects of vocabulary deteriorate with general impairment. The main defect of the study is, however, that it may have been contaminated, as the original estimate of deterioration may have been based partly on the way the subjects used words in interview.

Feifel (1949) tested Yacorzynski's hypothesis by giving a vocabulary test to one hundred and eighty-five normal and one hundred and eighty-five abnormal subjects matched for age, sex, education and Binet vocabulary as scored in the usual way. Placing the vocabulary responses into five categories as had been suggested by Yacorzynski, he found that the abnor-

malis gave significantly fewer synonym responses, and significantly more descriptive, inferior explanation, demonstration and illustrative responses.

An almost identical study was made by Moran, Moran and Blake (1952) on sixty-three schizophrenics also matched with sixty-three normals for age, sex, education and Wechsler vocabulary score. When Yacorzynski's method of analysis was used on the vocabulary responses, there were *no* significant differences between the groups in the number of synonym, use and description, explanation, inferior or error types of responses.

Rabin, King and Ehrmann (1955) tested twenty-five normals, twenty-five short-term schizophrenics and twenty-five long-term schizophrenics using the Wechsler vocabulary scale and the Ammon's Full Range Picture Vocabulary test. The latter test is non-verbal, and the answer is given by pointing to the appropriate picture. There was no differences between the normals and the short-term schizophrenics, but the long-term schizophrenics were worse on all the tests. They were *least* deteriorated on the Ammon's test although they were poor at explaining why they had pointed to the picture that they chose.

All these studies (except that of Moran, Moran and Blake, 1952) seem to be consistent with Yacorzynski's suggestions. Nevertheless, as a criticism of the use of vocabulary as a measure of past intelligence they are at least partly beside the point. It seems to be true that some deterioration in language function can be demonstrated among psychotics or deteriorated old people when special forms of vocabulary tests are devised, or when special systems of scoring are used for normal tests. However, this in no way disproves the often repeated original observation that vocabulary tests *scored conventionally* are not affected by mental disorder. It is probably safe to conclude that, if conventionally scored vocabulary tests are not unaffected, they are at least very little affected by mental illness.

The use of vocabulary tests as a measure of pre-illness level is perhaps the least important defect of indirect tests of deterioration, however. A much more important defect for their use with individual patients is their lack of standardization. Neither the Babcock, the Shipley-Hartford nor the Hunt-Minnesota test is adequately standardized. Babcock used the Binet vocabulary test, and relied on its standardization on children and very young adults. The standardization of the Shipley-Hartford is based almost entirely on normal people under twenty. It is well known that normal people continue to learn new words after twenty, just as they tend to perform less well on many non-verbal and speeded tests of intelligence. Thus, if the norms for eighteen-year-olds are used, the normal person of 50 will apparently have suffered a vast

¹ Shapiro and Nelson's study is typical of a few studies which have matched different diagnostic groups for age, and then found significant differences in vocabulary score. This does not prove, as the authors suggest, that vocabulary has deteriorated and is thus a poor measure of former level. As we have seen there is considerable evidence that different diagnostic groups did not have the same mean pre-illness general level in the first place.

amount of deterioration. That this is the case with the Shipley-Hartford scale has been demonstrated by Manson and Grayson (1947). Gilbert (1951) and Botwinick and Birren (1951) have demonstrated the same thing for the Babcock. This defect, however, does not make these tests useless for *comparative* studies between different abnormal groups provided the groups have been matched for age, so that not all the studies using these tests can be dismissed.

The Wechsler Deterioration Index is based on a different principle. It is merely the difference between those subtests which hold up with age, and those which decline with age in normal people. The rather curious assumption is that deterioration produced by psychosis or brain damage can be identified with the normal deterioration produced by age. The results of many of the early Binet studies make this unlikely (Wells and Kelley, 1920; Altman and Shakow, 1937; Malamud and Palmer, 1938; Davidson, 1938, 1939) since they found that only the *vocabulary* score failed to differentiate between normal and abnormal groups. Many Binet subtests similar to the Wechsler "don't-hold" tests were apparently affected by both psychosis and brain damage. By and large the Wechsler Deterioration Index has failed to produce consistent differentiation between normal and abnormal groups. For example, Schlosser and Kantor (1949) were unable to differentiate between fifty-six psychoneurotics, forty-five paranoid schizophrenics and forty-two residual non-paranoid schizophrenics. Garfield and Fey (1948), testing ninety-five cases, found no significant differences between six psychiatric groups, and no significant differences between psychotics and neurotics. Rappaport and Webb (1950) in the test-retest study of ten schizophrenics before and during illness already described, found a significant *negative* correlation between performance on the Wechsler "hold" tests and pre-illness I.Q. level, while the so-called "hold" test score was not significantly different from the I.Q. score obtained during illness. As one might expect, the deterioration index has such a high correlation with age (e.g. 0.60 reported by Johnson, 1947) that its practical clinical use would be impossible without age norms in any event.

Perhaps the most anomalous feature about the indirect measures of deterioration is the range of tests used to measure *present* general intelligence. One might imagine that the authors would all choose those tests which factorially were most representative of cognitive tests. Babcock, however, measures present level by means of a set of simple motor and mental speed tests, and tests of rote-learning ability because these tests were found to be *most* affected by psychosis. In other words, present general level is apparently equated with that aspect of impairment which is most marked. Shipley, on the other hand, uses a much

more conventional measure of *g*, a test of abstract reasoning using verbal material. Wechsler measures present-level only on those tests which are most affected by the ageing process. It would be surprising to find that these different indices of general deterioration were very highly correlated, and indeed they are not. Fox and Birren (1950), for example, found an insignificant negative correlation (-0.16) between the Babcock index and the Wechsler deterioration index, in fifty normal old people. Garfield and Fey (1948) found a correlation of only $+0.13$ between the Wechsler deterioration index and the Shipley-Hartford C.Q., using ninety-five cases with a wide range of psychiatric diagnoses, both neurotic and psychotic. Magaret and Simpson (1948), testing fifty mental patients, both psychotic and neurotic, found no significant correlation between the Shipley-Hartford C.Q. and the Wechsler deterioration index. Neither index correlated with a psychiatric rating of deterioration.

In spite of these shortcomings, the use of indirect measures of deterioration has produced a number of interesting findings. Although Babcock was the first to use vocabulary as a measure of former intelligence, the observation that vocabulary tends not to differentiate between normals and psychotics, while other tests do, was originally made on the Binet test. In 1920 Wells and Kelley gave the Binet test to one hundred and one psychotics (both schizophrenics and manic-depressives) and found that vocabulary was the highest subtest in the abnormal groups. This observation on the Binet test has been repeated many times. Altman and Shakow (1937) tested a number of groups of subjects matched for Binet mental age. The discrepancy between the vocabulary and the remaining tests was expressed as a difference between two standard scores. The results are shown in the following table—

TABLE VI.6
BINET STANDARD SCORE MINUS VOCABULARY
STANDARD SCORE
(After Altman and Shakow)

Group	Mean difference	S.D.
<i>Matched for M.A.</i>		
56 normals	-0.220	0.735
56 delinquents	-0.045	0.758
56 co-operative schizophrenics	$+0.265$	0.750
<i>Matched for M.A.</i>		
30 normals	-0.398	0.851
30 delinquents	-0.292	0.908
30 non-co-operative schizophrenics	$+0.706$	1.121

In both cases the schizophrenics differ from the normals at a very high level of significance. The two

groups differ markedly in general level, so that the finding seems to hold good at two quite different M.A. levels.

Malamud and Palmer (1938) tested one hundred deteriorated schizophrenics, one hundred brain-damaged cases and one hundred normals all matched for Binet M.A. (the normals were mental defectives to obtain the matching). They found the following Binet-vocabulary discrepancies (in months of mental age)—

normal defective	= 0.84 (S.D. 0.141)
deteriorated schizophrenics	= 38.44 (S.D. 1.507)
brain-damaged	= 42.42 (S.D. 1.367)

Davidson (1938) found an average difference of thirty months of mental age between vocabulary and Binet score in seventy-one schizophrenics, while two hundred and two normal controls showed a mean difference of only three months. The amount of the discrepancy was related to the doctors' ratings of deterioration for twenty-two cases studied.

Davidson (1939) found, as might be expected from the lack of age norms for the Binet, that the amount of discrepancy was also a function of age, with larger discrepancies occurring among the older. Nevertheless discrepancies still differentiated the different groups when age was controlled, as shown in the following table—

TABLE VI.7
VOCABULARY—BINET DISCREPANCIES IN
M.A. UNITS
(After Davidson)

Group	Age		
	below 20	20-40	over 40
18 defective manic-depressives	+ 11	+ 3	- 12
215 non psychotic defectives	0	- 1	- 6
172 defective epileptics	- 1	+ 3	- 12
18 defective schizophrenics	- 2	- 17	- 12
21 psychotic epileptics	-	- 21	- 32
39 manic-depressives	- 12	- 24	- 26
50 non-psychotic epileptics	- 12	- 27	- 17
27 schizophrenics	- 45	- 44	- 59

This table agrees in some respects with the findings on present general level for these different groups, and it is plausible that the discrepancies are partly a function of general deterioration. The non-psychotic epileptics represent a slight anomaly as they are among the most deteriorated. However, we cannot be sure how many of these institutionalized cases were brain-damaged. It is also interesting that the two

defective psychotic groups are least deteriorated. Either the very dull deteriorate less, as they can't become appreciably worse on tests of this sort, or these groups have suffered an equal impairment on vocabulary and were thus judged always to have been defective.

Shakow (1946) also notes that the Binet-vocabulary discrepancy is a function of age, and reports a correlation of + 0.72 between age and discrepancy for a group of twenty-five schizophrenics.

We can conclude from these Binet studies that there is strong and consistent evidence for a large discrepancy between Binet vocabulary scores and Binet M.A. scores, which is not an artefact of age in psychotic groups, particularly schizophrenics. What this discrepancy is due to, ultimately, it is not possible to say. However, it is strong indirect evidence that some general intellectual deterioration is produced by psychosis.

Similar results have been obtained in a number of studies comparing vocabulary scores with other tests of general intelligence. Simmins (1933) tested two hundred mental patients and twenty controls on the Binet vocabulary test and a group of visual-perceptual g tests used by Spearman. She found no evidence for lower vocabulary scores among the abnormals. Using an arbitrary criterion for deterioration in terms of the magnitude of vocabulary - g discrepancies, she found the following proportions of deteriorated patients in different diagnostic groups; hysterics 0 per cent, anxiety neurosis 14 per cent, manic-depressives 41.5 per cent, *dementia praecox* 45 per cent, delusionals 56.5 per cent, melancholics 62 per cent. Harbinson (1937) using the same tests, found similar results except that, on these criteria, only about 30 per cent of schizophrenics are deteriorated whereas 80 per cent of melancholics are deteriorated. The failure, however, of either study to allow for age could clearly account for such discrepancies.

Lidz, Gay and Tietze (1942) used the discrepancy between the Koh's block score and the Binet vocabulary, and found evidence for deterioration in schizophrenics. Rabin (1944a) compared the Binet vocabulary score with the Wechsler-Bellevue I.Q. and found that psychotics had a much larger discrepancy than neurotics. Klehr (1949), using three Wechsler subtests, found that six out of twelve schizophrenics had both "comprehension" and "similarities" test scores below their vocabulary level. This was true of only 19 per cent of a small group of normals and defectives. Hunt and French (1949) report similar results for forty-two schizophrenics, three hundred and fifteen normals and fifty-eight defectives on the same tests.

Hall (1951) gave sixty-seven normals and thirty-six schizophrenics the Wechsler vocabulary test, and a

large battery of tests of the "ability to abstract." The vocabulary score did not differentiate the groups, whereas the abstraction score differentiated at the 1 per cent level.

Himmelweit (1945) reports that, among the army service breakdown neurotics tested at Mill Hill, there was a significant tendency (based on 1,821 men and 987 women) for introverted neurotics to obtain higher vocabulary scores, and extraverted neurotics higher Matrices scores.

Although the Babcock-Levy test uses quite a different measure of present level (i.e. speeded mental and motor tests and tests of rote learning) a number of

researches have found results very similar to those reported above. The findings on the Babcock Efficiency Index are best summarized by a table.

These results, taken at face value, again suggest that psychosis produces some degree of intellectual deterioration. There are no consistent differences between manic-depressives and schizophrenics. In these studies manics and depressives do not appear to have been treated separately from manic-depressives, but there is no evidence on this test that the cyclic disorders are free from deterioration.

Within the schizophrenic groups again there is a considerable range of results, and some of the undif-

TABLE VI.8
BABCOCK "EFFICIENCY INDICES" IN DIFFERENT DIAGNOSTIC GROUPS

Group	No. of cases	Mean index	Median index	S.D.	Range	Investigator
Normals	264	0.0	+ 0.1	1.18		Babcock, 1930
Normals	228		+ 0.5		— 3.4 to 3.2	Babcock, 1933

ferentiated cases are probably early schizophrenics. In these studies there are no striking differences between hebephrenics, simple schizophrenics, catatonics and paranoid schizophrenics. All seem about equally deteriorated. However, this is not really inconsistent with studies which suggest that hebephrenics have the lowest tested I.Q. when ill. If we accept that hebephrenics as a group are those who have always been duller, there is no reason to suppose that they *deteriorate* more. The main discrepancy lies in the paranoid subgroup, whose rate of deterioration was seen to be less than the other groups in previous studies.

The variable results quoted for epileptics are not surprising, as the presence or absence of brain damage is not controlled in these studies.

The Babcock test also suggests a fact which has *not* been suggested by the other studies, namely that neurotics show a mild degree of deterioration. Babcock (1940) reports a special investigation into the relationship between neuroticism and the efficiency index. She gave three hundred and thirteen normal subjects the Babcock test and the Bernreuter neurotic inventory. Correlations between the subtests of the Bernreuter and the efficiency index were in the expected direction, but insignificant. There was, however, a significant tendency for those scoring in the top quartile for neuroticism to be less efficient than those in the bottom (stable) quartile.

The fact that the Babcock test does not agree in detail with other studies of general deterioration is not surprising in view of the nature of the Babcock test items. The Babcock is largely a test of speed and differences in efficiency indices between groups may be due largely to this relatively specific function. This will be dealt with later.

Finally it should be noted that the efficiency index is clearly related to age, and that most of these studies found it especially important to match their groups for age. Normal old people show a great deal of deterioration on this test. It is clear that it could not be used as a clinical tool without age norms.

There have been relatively few studies investigating deterioration in functional groups using the Shipley-Hartford scale. Shipley and Burlingame (1941) tested three hundred and seventy-four patients, and obtained the following order for different clinical groups (from least to most deteriorated): normals, neurotics, depressives, manics, schizophrenics, involuntions. Unfortunately, unlike the better studies with the Babcock, the groups were not matched for age, and mean age differences could considerably affect the order of the groups. Garfield and Fey (1948) gave the Shipley-Hartford to thirty-five schizophrenics, sixteen neurotics, eight psychopathic personality cases, eight psychotics and twenty-three non-psychotic cases.

The C.Q. did not differentiate significantly between psychotics and neurotics, although the neurotics were slightly better.

The Hunt-Minnesota test (Hunt, 1943*a*, 1943*b*, 1944; Aita *et al.*, 1947; Armitage, 1946), while identical in rationale and general structure with the other tests of deterioration discussed, has so far been used only in the study of the effects of brain damage.

SUMMARY OF FINDINGS ON GENERAL INTELLECTUAL LEVEL

The data presented above suggest the following general conclusions—

1. Most studies suggest that neurotic disorders produce very little deterioration of general level. A small amount of impairment is however found on the Babcock test. While army service breakdown neurotics are below average in intelligence, civilian neurotics are both brighter and more homogeneous than the general population. Introverted neurotics tend to be brighter than extraverted neurotics.

2. Epilepsy as such produces no general deterioration, although if the convulsions are the result of brain damage, considerable general impairment can occur.

3. Psychosis produces a considerable degree of general deterioration, which is related to the severity of the illness and is probably progressive if the patient does not recover. Recovery, however, leads to considerable improvement.

4. By and large, affective disorders seem to have the same general level, when ill, as schizophrenics. However it is possible that manics and depressives suffer *more* general deterioration than the average schizophrenic group, since there is some evidence that their mean pre-illness I.Q.s are average or above. There is some very slight but conflicting evidence that cyclic forms of affective disorder (manic-depressive psychosis) do not produce deterioration. It is also possible that "Involuntary Depression" produces very little general impairment, although data are few.

5. Schizophrenics in general are so heterogeneous that there is no real reason to regard them as suffering from a single disease entity, at least as far as cognitive results are concerned. On average, schizophrenics are duller than normal before becoming ill, and therefore on average may have deteriorated less than manics and depressives. Their mean illness level is just below average, and similar to that of the affective disorders. On average, without remission, schizophrenia produces a steady progressive deterioration.

Paranoid schizophrenics are of average I.Q. before illness, and while they, too, suffer a progressive deterioration in level if they do not recover, this deterioration is much slower than in other schizophrenics.

The term hebephrenia, when used, appears to refer

to a group of schizophrenics whose pre-illness I.Q. is low average to borderline defective. Hebephrenics also deteriorate as their illness progresses.

6. By and large, a high level of I.Q. while psychotic is a good prognostic indication.

From these findings we can only speculate about the relationship between general level and specific symptoms. Perhaps two or three guesses are possible. Systematic paranoid elusions and ideas of reference may occur mainly in people of average or above average pre-illness level (some involuntional melancholics, some paranoid schizophrenics, some early, schizophrenics and a few depressives) who tend *not* to deteriorate rapidly with continued illness, nor to have very much below average levels while ill. It is

conceivable that the cognitive disability associated with these symptoms is relatively specific.

People of very low pre-illness intelligence, when they become psychotic tend to exhibit mood swings and silly, bizarre or grotesque forms of behaviour which in some cases leads to the label hebephrenic.

People who develop periodic catatonic stuporous conditions tend to have considerable associated intellectual deterioration.

The writer will attempt in the second section of the chapter to discover if possible what specific abnormality or combination of abnormalities of mental function could be responsible for these overall results for general level which are themselves completely ambiguous.

II. THOUGHT PROCESSES

VARIABILITY OF PERFORMANCE

It is quite possible to postulate individual differences with respect to "variability" of test performance. The more variable individuals would show a wider range of performance on the same test given on a number of occasions. Differences in variability would, however, be difficult to use as an explanation of *mean* differences in test performance. There is no reason why variable people should not produce as strikingly good performances on some occasions as they produce bad performances on others. Variability as used here is not equated with "distractibility," as the latter would produce a mean (if variable) decrease in performance.

Nevertheless variability has for many years been used as an explanation of general cognitive deterioration especially in schizophrenia.

A number of early studies investigated variability in different clinical groups by obtaining measures of "scatter" from the Binet test. Usually scatter was defined as the difference (in mental age units) between the Binet "basal" age (i.e. the age level at which *all* the tests were passed) and the age level at which the last item was passed. Thus variable people had large differences, while people with homogeneous performances had small differences. There were, however, minor variations in the method of assessing scatter.

Wells and Kelley (1920) were among the earliest to find that psychotics had an unusually large amount of scatter on the Binet test. Wallin (1927) reported similar results even earlier, and also found that neurotics had slightly more Binet scatter than had normals. Harris and Shakow (1937) reviewing the literature up to that time, point out that abnormally large Binet scatter has been claimed for the feeble minded, for *dementia praecox*, for alcoholism, for psychopaths, for manic-depressives and for organics.

They point out, however, that none of the early studies used an adult control group, but made use of the data for children. In 1938 Harris and Shakow themselves performed a large-scale study of Binet scatter using one hundred and fifty-four schizophrenics, one hundred and thirty-eight delinquents and one hundred and thirty-three normal controls. They found that Binet scatter was a function of mental age, and when this was controlled, the groups were not differentiated significantly. The implication is that Binet scatter is artificially reduced by the floor and ceiling of the test. Nevertheless Malamud and Palmer (1938) found that one hundred deteriorated schizophrenics had significantly more Binet scatter than one hundred defectives matched for mental age.

As the Wechsler-Bellevue became more popular, a number of studies of scatter on this test were reported. Olch (1948) defined Wechsler scatter as the average subtest deviation (ignoring direction) from the individual's mean subtest score. She reported that sixteen young schizophrenics had a scatter score of 9.8, and sixteen older schizophrenics had a score of 10.3. This was significantly larger than the mean scatter scores for young normals (3.2) and older normals (3.4). Magaret (1942), defining Wechsler scatter in the same way, found a mean scatter score of 11.2 for a group of eighty schizophrenics, much larger than the score of 2.7 obtained by normals of the same age. Schnadt (1952), reporting the results of one hundred neurotics, found that Wechsler scatter was a function of level of intelligence (a finding similar to Harris and Shakow's for the Binet).

Monroe (1952) defined Wechsler scatter as the individual's subtest standard deviation (about his own subtest mean). He tested one hundred and forty-four schizophrenics, one hundred and thirty-six psychoneurotics and seventy-two normals. Neurotics and

normals did not differ in scatter, but schizophrenics of low intelligence had a large amount of scatter.

It seems probable then, that not all the differences found can be dismissed as due to differences in I.Q. There is evidence that schizophrenics have more scatter on the Wechsler and the Binet than normals, although it is doubtful if neurotics and normals differ.

This finding is, however, completely ambiguous. As Eysenck (1947) has pointed out, a larger scatter of subtest scores within a diagnostic group can be due to one of two things: either the individuals are more variable in their performance of all the tests, or the tests have much lower intercorrelations within the group. If the latter is the case, we might postulate some alteration in the relationships between mental functions in the group, but we could not say it is more variable in performance.

Fortunately there are a number of studies which investigate variability separately. Eysenck (1947) investigated the variability of test performance of large groups of neurotics and normals on the Matrices test. This test contains five sets of similar items. The index of variability used was the sum of each individual's deviations (regardless of direction) from the median score for each set obtained by individuals

with the same total Matrices score. A group of one hundred normals had an average index of variability of 4.2, while a group of two hundred neurotics had an average index of 3.7. The difference is not statistically significant. A group of four hundred and seventy-five hysterics had an average index of 3.81, while nine hundred and four dysthymics had an average index of 3.72. Again the difference is insignificant. Thus there is no evidence that neurotics are abnormally variable, nor is there evidence of a difference in variability between introverted and extraverted neurotics.

Margaret Davies Eysenck (1945) administered twenty cognitive tests to eighty-four senile dementia patients, and retested them four months later. The coefficients of reliability were all high, and there was no evidence for greater variability among senile dementia patients than among normals.

Holzberg and Deane (1950) tested twelve schizophrenics and twelve neurotics matched for age, I.Q. and education on the Wechsler-Bellevue. Using a measure of *intra-test* scatter, they found that schizophrenics were significantly more variable than neurotics. This is, however, the only article reporting abnormal variability in schizophrenics. Derner, Aborn and Canter (1950), reviewing the literature on

Wechsler reliability, conclude that there is no evidence that schizophrenics are more variable than normals in terms of test-retest reliability.

The reliability data for the Wechsler-Bellevue are summarized in Table VI.9.

Most of the reliability studies employing the Wechsler seem to have used normals or schizophrenics. The one study (Rabin, 1944*b*) using manic-depressives and neurotics unfortunately combines them. The best matched control group is that of Webb and De Haan (1951). The reliabilities they report for their paranoid schizophrenics and normals are lower than those of the other studies, because an uncorrected split-half coefficient was used. The two groups are very similar however. The normals reported by Derner, Aborn and Canter (1950) are not a very adequate control group for the Rabin (1944*b*, 1944*c*) and Hamister (1949) schizophrenic groups, because they were college students of above average intelligence. Nevertheless the differences are very small on the whole.

Although the literature is not extensive we can conclude then, that there is no evidence that the performance of any abnormal group is more variable than that of normals. It, therefore, seems clear that we cannot explain any of the differences in general level in terms of variability of performance.

If this is the case, the finding that schizophrenics have a greater Binet and Wechsler scatter than normals must mean that the subtests of these scales have a lower mean intercorrelation within the schizophrenic group.

There are very few studies of the comparative *size* of cognitive test intercorrelations within normal and abnormal groups. Rabin (1944*a*) correlated the Binet vocabulary with the Wechsler-Bellevue I.Q. within three groups of patients and a normal group. His findings are summarized in Table VI.10.

TABLE VI 10
CORRELATION (r) BETWEEN BINET
VOCABULARY AND WECHSLER I.Q.

Group	Full scale I.Q.	Verbal I.Q.	Per- formance I.Q.
90 schizophrenics	0.75	0.83	0.54
18 manic-depressives	0.77	0.79	0.67
24 neurotics	0.68	0.76	0.24
52 normals	0.86	0.88	0.75

These correlations are lower for the schizophrenic group, as we would expect. It is surprising, however, that the neurotics produce the lowest correlations. There was no evidence for increased test scatter in

neurotics, and this finding may reflect some peculiarity of this rather small neurotic sample.

Decreased correlations between some cognitive tests among schizophrenics would suggest that a change in the functional interrelationships between the measures is produced by schizophrenia.

It has already been pointed out that one of the most anomalous facts in psychology seems to be that cognitive tests tend to have such high intercorrelations even though cognition refers to such a wide range of mental operations performed on such a wide range of test material. One explanation for this may well be that the average cognitive test is a very impure measure indeed. The ultimate score is determined by the interaction of a large number of different processes which tend to overlap between one test and another. Furneaux's work seems to demonstrate this clearly. For example, most cognitive tests are partly a function of "mental speed," but none of them are uncontaminated measures of speed. When tests are carefully designed to measure only *one* cognitive process, the size of their intercorrelations seems to decline sharply (e.g. the very low correlation between speed and error, cf. Furneaux).

It is possible then to account for a decrease in correlation within a schizophrenic group in the following way (assuming of course that the results are not merely an artefact of homogeneity of one of the variables among schizophrenics, an unlikely finding in view of the increased variances usually reported for this group). Let us suppose that in normals the score on Test 1 is equally determined by three unrelated functions A, B and C. Let us suppose the score on Test 2 is determined equally by three unrelated functions B, C and D. The two test scores are affected by B and C in common, and this will produce a substantial correlation within the normal group. One factor which could *decrease* the size of the correlation within the schizophrenic group would be the addition of a fourth determinant of the score on Test 2 for this group without any change in the determinants of the score on Test 1. The situation can be expressed diagrammatically as follows—

Test 1.	A	B	C			
Test 2.		B	C	D	normals	$r = x$
Test 1.	A	B	C			
Test 2.		B	C	D	E	schizophrenics $r < x$

The intrusion of function E into Test 2 for the schizophrenic group could easily be the result of some specific dysfunction. Let us suppose that E is an ability essential to the performance of Test 2. Let us suppose, however, that all normal people have very similar amounts of it, and are relatively homogeneous in this respect. Let us also suppose that, while a

normal quantity of E is essential to do Test 2 perfectly, an excess of E is of no further help. If one has this critical amount of E (as all normal people do), test performance is *entirely* dependent on other factors (B, C and D). If, however, one drops *below* this critical amount of E ability, performance on Test 2 becomes increasingly affected. Thus E becomes an additional determinant of score in the schizophrenic group, and individuals within the group tend to vary in score depending on how much E they have. In other words, E is some specific disability in schizophrenics which, because of its severity, becomes an additional factor in the performance of many tests which are normally quite uninfluenced by this particular ability.

We should, therefore, find among schizophrenics at least two groups of tests, some influenced by a disability and some unaffected by it. It will be the correlations between the affected and the unaffected tests which will be reduced within the schizophrenic population. From the data so far discussed, it seems unlikely that vocabulary is much affected in schizophrenia. Therefore in Rabin's (1944a) study it is probably the Wechsler scores in schizophrenics which are influenced by some additional factor (a disability) not operative in the normal group.

Explaining abnormal scatter in schizophrenia has thus led us to postulate one (or more) specific intellectual disabilities among schizophrenics. Their possible nature will be discussed in later sections.

There is one factorial study of the Wechsler-Bellevue (Cohen, 1952a, 1952b) which supports the notion that intercorrelations are different within a schizophrenic group. Unfortunately the author does not give the matrix of correlations, so unusually *low* correlations cannot be demonstrated. Cohen performed separate factor analyses of the Wechsler-Bellevue subtests for one hundred neurotics, one hundred schizophrenics and one hundred brain-damaged cases. Using Thurstone's simple structure analysis he obtained a similar factor structure for each of the three groups. There were three main (oblique) factors which he labelled "Verbal," "Non-verbal" and "Freedom from Distractibility" (or "immediate memory span"). There was in addition, a second order factor which he labelled g. For the schizophrenic group, unlike the neurotics, "comprehension" is a poor g test (presumably showing reduced correlations with other variables). "Arithmetic" is also a poor g test for schizophrenics. However, "Digit Symbol" is a relatively good g test for this group. Other differences were found, and there is ample evidence for differences in the interrelationships between the tests when the schizophrenic group is compared with the neurotic group.

The other main factorial studies of cognitive tests

in abnormal groups are concerned with patients with senile deterioration. In these studies, quite different findings have emerged. There is a tendency for the intercorrelations between the Wechsler subtests to *increase* in the senile age range (55+) (Balinsky, 1941; Birren, 1952). Parallel with this increased correlation there is a general change in the factorial composition of the Wechsler. Cohen (1957) discovered that: "In the 60-over 75 group the Memory factor undergoes a sharp increase in variance at the cost of the general factor. Thus, in aged subjects, intellectual performance, even on verbal tests, becomes dependent to a noteworthy degree on memory ability." This is consistent with findings by Balinsky (1941) and Birren (1952). There is evidence that the ability to memorize material is one determinant of cognitive score at all ages. However, it is likely that most young normals are sufficiently good at memorizing to make their cognitive performance dependent almost entirely on other factors. However, as the ability declines with age, older people find it increasingly difficult to memorize material. Thus they tend to be unable to learn new test instructions and new methods of manipulating material they have never seen before (e.g. Blocks). This becomes so handicapping that as the ability to memorize drops below a certain value it becomes an increasingly important determinant of many test scores. The situation can be illustrated by the following diagram (where A, B, C and M—memory—are relatively independent determinants of the scores of Tests 1 and 2)—

Test 1.	A	M	B	Young normals
Test 2.		M	B	$r_{12} = x$
Test 1.	A	M	M	Old normals
Test 2.		M	M	$r_{12} = x + \Delta x$
Test 1.	A	M	M	Senile dementia
Test 2.		M	M	$r_{12} = x + \Delta x + \Delta x$

As memory accounts for more and more of the variance of Tests 1 and 2, so the correlation between the two increases.

This general picture is consistent with the results of Margaret Davies Eysenck (1945) who uses the terms "fluid" and "crystallized" ability following Cattell (1943). She found a tendency for eighty-four senile dementia cases to do poorly on tests of fluid ability. If we can assume that learning is much more important in the latter tests (e.g. Raven's Matrices as contrasted with Vocabulary tests), the results are entirely consistent. Inglis (1957) has developed this theory in a recent paper and presents evidence in support of it which will be discussed later.

It is clear then, that a specific abnormality can lead to an increase in correlation between two tests which are both influenced by it, but a decrease in the

correlation between two tests when the abnormality has become an important new determinant of the score on one, but not of the score on the other. We can expect considerable alterations in the intercorrelations of tests in abnormal groups. However, whether they decrease (as in the case of the tests discussed for schizophrenics) or increase (as in the case of some tests among seniles) depends *entirely* on the make up of the tests. No general prediction can be made about either group.

Summary and Conclusions

1. What evidence exists suggests that psychiatric groups, both neurotic and psychotic are no more variable in their test performance than normals. Differences in variability cannot explain the general cognitive abnormalities so far dealt with.

2. There is, however, evidence for an increased scatter of the subtest scores of the Binet and the Wechsler-Bellevue in schizophrenic groups. This must be due to a decrease in correlation between these subtests for this group. There is evidence that the correlation between a vocabulary test and the Wechsler I.Q. in a schizophrenic group is in fact reduced.

3. The cause of a reduced correlation within a psychotic group could be the influence of some specific disability which is not usually a determinant of test score, but which becomes so because of its severity. Tests affected by the disability thus show reduced correlations with tests unaffected by it.

4. A specific disability can lead to an increase in test intercorrelation when the disability affects all the tests concerned. This seems to be the case in old people and senile dementia patients. As they become very poor at rote learning, this becomes an increasingly important determinant of their score on all tests, and the intercorrelations between all the tests become higher.

CONTENT

There are no investigations which report differences between abnormal groups which are clearly due to differences in their ability to solve problems with different *content*. Those studies which have been made are inconclusive since content is only one of the variables which could produce differences between the tests given.

Most of the data available are concerned with differences in Wechsler-Bellevue subtest scores. There are many studies of Wechsler-Bellevue "profiles" in different groups (Altus and Clark, 1949; Carp, 1950; Collins, 1951; Brecker, 1946; Dana, 1957; Garfield, 1948, 1949; Gilliland *et al.*, 1943; Goldman *et al.*, 1946; Hamister, 1949; Harper, 1950a, 1950b; Jastak, 1953; Johnson, 1949; Klein, 1948; Kogan,

1950; Levine, 1949; Lewinski, 1945a, 1945b, 1947; Magaret, 1942; Olch, 1948; Patterson, 1946; Rabin, 1941, 1942, 1944a, 1944b, 1944c; Rapaport *et al.*, 1945; Senf *et al.*, 1955; Shoben, 1950; Sloan and Cutts, 1945; Stotsky, 1952; Warner, 1950; Webb and De Haan, 1951; Weider, 1943; and Wittenborn, 1956). Kogan (1950), reviewing eighteen of these studies concludes that there is no satisfactory evidence for specific Wechsler profiles for different clinical groups. Wittenborn (1949) agrees with this general conclusion. Both these and other authors (e.g. Jones, 1956) point out that even if clear cut "profiles" did exist for groups, they could not be used for "diagnostic" purposes with individuals because of the large error variance of Wechsler subtest scores. No one, however, appears to have computed weighted subtest means and standard deviations from the individual studies reported in the literature to determine to what extent profiles tend to cancel out when the data are combined.

Table VI.11 combines the data reported in the literature for Verbal I.Q.-Performance I.Q. discrepancies in different groups. (This table is based on the following studies: Altus and Clark, 1949; Carp, 1950; Dana, 1957; Harper, 1950a, 1950b; Lewinski, 1945b, 1947; Magaret, 1942; Olch, 1948; Rabin, 1944a, 1944b; Rapaport *et al.*, 1945; Stotsky, 1952; and Warner, 1950. Many studies had to be omitted because insufficient data were published.)

Epileptics	25	98.64	13.10	100.76	11.34
Delinquents	53	82	—	98	—

* Based on fewer cases. The schizophrenic S.D. is probably a slight underestimate being based on two hundred and eighteen cases whose mean Verbal I.Q. was 100.3 and whose mean Performance I.Q. was 101.4. The neurotic S.D. is not as representative, being based on only a hundred cases (Mean Verbal I.Q. = 96.9, mean Performance I.Q. = 98.92). The inverted neurotic S.D. is based on only twenty-five cases (mean Verbal I.Q. = 101.68, mean Performance I.Q. = 103.32).

The largest differences tend to occur in the smallest and least representative samples. The 16-point difference for the delinquent group is the only strikingly large difference, and while it is based on a fairly small unrepresentative sample, it may indicate a tendency for the delinquents to have a low educational attainment, thus handicapping them on verbal items.

The large depressive difference of thirteen I.Q. points is based on only eight cases. For the rest, the difference seldom exceeds two I.Q. points, and while it may be statistically significant¹ in some cases because of the large numbers, it represents a very trivial difference indeed in terms of the comparative ability on the two sorts of material.

The simple schizophrenics, the catatonic schizophrenics and the hebephrenic schizophrenics have approximately a four-point difference in favour of the Verbal scale. These may be the most deteriorated of the schizophrenic groups, and it is possible that the Performance scale contains items which deteriorate slightly more rapidly with this disorder. Because of the large number of determinants of both Verbal and Performance I.Q. scores however, these findings are completely inconclusive.

One group not represented in the table is senile dementia. There is considerable evidence (Inglis, 1958) that these patients have a mean discrepancy in favour of the Verbal I.Q. However, since this is probably not a function of the "content" of the material as such, it will be discussed later.

Table VI.12 combines the data reported in the literature for Wechsler subtest performance. Beneath the results for each psychiatric group are the data for normals of the same age, as reported by Wechsler (1944). (This table is based on the following studies: Carp, 1950; Collins, 1951; Dana, 1957; Garfield, 1949; Gilliland *et al.*, 1943; Hamister, 1949; Harper, 1950a, 1950b; Lewinski, 1945b, 1947; Magaret, 1942; Olch, 1948; Rabin, 1942, 1944b; Rapaport *et al.*, 1945; Stotsky, 1952; Warner, 1950. Many studies had to be omitted because insufficient data were published.)

These "profiles" are surprisingly regular. The mean subtest differences appear to diminish as the number of cases on which the profile is based increases.

The most reliable data are for schizophrenics. Their highest subtest scores are on Vocabulary (9.73) and Information (9.32). Both tests merely involve the recall of information learned in the past, and while it is not surprising that these tests are least affected, there is no evidence that the *content* of the material as such as anything to do with it. The lowest subtest

scores in the schizophrenic group are Digit Symbol (7.07), Digit Span (7.53) and Arithmetic (7.55). While it is possible to postulate a specific inability to deal with numerical material, alternative explanations are possible. The difference between highest and lowest subtest score for this group is 2.66 weighted score points. The mean Vocabulary score for normals of this age is not available, but normals have a difference of 0.6 points between Information and Digit Span, suggesting that at least this much of the difference can probably be attributed to age.

The other schizophrenic groups are not dissimilar in that Information is always the highest subtest score (Vocabulary scores are lacking). Digit Symbol, Digit Span and Arithmetic tend throughout to be the lowest test scores, although the order varies from group to group. Hebephrenics have relatively low Comprehension scores. Since the mean differences are so small, however, and the cases relatively few, much detailed speculation seems pointless.¹ By and large these findings are consistent with the subtest rank order reported by Jastak (1953) for eighty schizophrenics (unfortunately mean scores are not given). Johnson (1949) also found that Digit Span and Digit Symbol were among the lowest subtests in a group of sixty-nine schizophrenics (again means are not reported).

The number of cases in the affective groups are very small. However, test profiles are fairly regular. Information, Comprehension and Similarities tend to be higher than tests involving speed (e.g. Digit Symbol) or manipulation, but one cannot necessarily conclude that these groups find verbal problems easier.

Epileptics have a relatively regular profile, and their slight deviations are difficult to account for in terms of the "content" of the material.

The only large neurotic group is the Introverted one. Here the highest subtest score is Vocabulary (11.77) and the lowest, Digit Span (9.60), a difference of 2.17 weighted score points. Since normals at this age have a discrepancy of 0.95 between Information and Digit Span (Vocabulary data are lacking for normals), much of this can be attributed to age. The profile does not suggest a specific difficulty with any particular sort of test material.

Because of the fact that the Wechsler-Bellevue subtest scores are particularly "impure" factorially, it is one of the worst tests with which to assess the effect of test "content" as such. Some other studies are available however. Hunt and Older (1944) gave the revised Kent Emergency Test ("information" and "reasoning ability") a verbal "opposites" test, an

¹ No attempt has been made in any of these tables to assess levels of significance. The correct assessment of such levels involves the correlations between the tests for these groups, data which are seldom given.

¹ Again it is not possible to calculate levels of statistical "significance" through lack of data, particularly the test inter-correlations for each group. Even if these were available however, the number of mean comparisons possible would make a suitable statistical "null hypothesis" very elaborate indeed. Simple *t* tests would obviously be misleading.

* Based on fewer cases. The schizophrenic subtest standard deviations are based on an N of 516, except for the "Vocabulary" test, where the N is 258. The means of these smaller schizophrenic groups for the subtests are: Information = 9.3, Comprehension = 8.9, Arithmetic = 8.0, Digit Span = 7.6, Similarities = 8.5, Vocabulary = 9.5, Picture Completion = 8.6, Picture Arrangement = 7.9, Object Assembly = 9.3, Block Design = 9.2, Digit Symbol = 7.1. The epileptic subtest standard deviations are based on an N of 400. The means of this smaller epileptic group are: Information = 10.98, Comprehension = 11.88, Arithmetic = 9.66, Digit Span = 9.17, Similarities = 11.30, Vocabulary = 11.08, Picture Completion = 10.67, Picture Arrangement = 10.19, Object Assembly = 10.56, Block Design = 11.21, Digit Symbol = 10.10.

"easy directions" test and an "arithmetic reasoning" test to eighty-three cases of psychopathic personality, thirty-seven organics and thirty-one schizophrenics. The psychopaths did better on oral and worse on written tests. Otherwise there were no differences between the groups. There is no support for the hypothesis that schizophrenics find problems involving numerical material more difficult.

Penrose (1945) gave the Canadian Army "M" test to groups of affective disorders and schizophrenics. The results are shown in Table VI.13, which gives "standard scores" based on an army standardization sample of 9,000 males.

since other tests utilizing meaningful pictorial material are relatively well done. It is possible that the particular type of reasoning involved (inductive generalization) could be especially bad in this group. This will be discussed in the next section.

The author draws attention to one rather curious feature in these results. The male schizophrenic profile is very similar to the normal female profile. (Indeed the profiles correlate significantly.) It is as if male schizophrenics have a feminine pattern of aptitudes before they become ill and that illness merely reduces the general level. Since pre-illness studies are lacking, however, this must remain speculative. There

TABLE VI.13
"M" TEST PROFILE FOR PSYCHOTIC GROUPS
(After Penrose)

Subtest	Normal females (N = 50)	Schizophrenic females (N = 25)	Schizophrenic males (N = 55)	Affective females (N = 17)	Affective males (N = 35)
1. Picture completion	- 0.20	- 1.53	- 1.44	- 1.30	- 0.66
2. Pictorial absurdities	- 0.26	- 1.37	- 1.18	- 1.44	- 0.50
3. Figure construction	+ 0.15	- 0.80	- 0.94	- 0.79	- 0.76

6. Arithmetic	+ 0.15	- 0.55	- 0.56	- 0.74	- 0.15
7. Vocabulary	+ 0.64	+ 0.11	- 0.13	+ 0.11	+ 0.11
8. Verbal analogies	+ 0.48	- 0.58	- 0.77	- 0.70	- 0.31
Mean	- 0.06	- 0.93	- 0.83	- 0.89	- 0.34

Unfortunately the author does not give the age of the groups, and age differences may not have been controlled. There are obvious sex differences on these tests, as seen from the results for normal females, and these must be allowed for in assessing the data for psychotic females.

As usual, schizophrenics do best on Vocabulary where their scores are very close to the normal average. They obtain below average, but very similar scores on Figure construction, Tool recognition, Mechanical information, Arithmetic and Verbal analogies. These tests differ both in content and the type of reasoning required, although all are timed. There is no evidence again that numerical content, as such, produces especially low scores among schizophrenics. They are, however, especially poor at Picture completion and Pictorial absurdities. It seems unlikely that this is due to the content of the tests,

is no tendency for schizophrenic females to have a particularly exaggerated female profile.

The affective groups also do best at Vocabulary. They obtain relatively poor, but similar scores on Tool recognition, Mechanical information, Arithmetic and Verbal analogies. There is no evidence that the affective group is better at tests using verbal material. Like the schizophrenics they are worse at Picture completion and Pictorial absurdities, perhaps for the same reason. However, they are also bad at Figure construction, a typical test of spatial reasoning. It is interesting that sex differences in aptitude are larger than the differences in profile between the two psychotic groups which are essentially very similar.

Perhaps the most satisfactory content study is one by Binder (1956) who gave the S.R.A. tests of Primary Mental Abilities (Thurstone) to one hundred and twenty male schizophrenics and a total of two hundred

and fourteen normal controls. The groups did not differ significantly in age or years of education. The results are given in Table VI.14.

All these tests are timed. There are no striking differences between the tests, and no evidence that schizophrenics are better at tests involving one sort of content than another. At both age levels, normals have a fairly uniform superiority. (The only exception

sort of test content especially difficult. The differences in test scores discussed can be explained more easily in other ways.

TYPE OF PROBLEM

In the introduction it was pointed out that cognitive tests can require the subject to perform a wide range of different operations. Unfortunately data are not

TABLE VI.14
P.M.A. SCORE IN SCHIZOPHRENICS AND NORMALS

Younger Groups (Schizophrenic mean age = 29.2, S.D. = 5.6, N = 55, normal mean age = 27.8, S.D. = 5.2, N = 59)

Reasoning	5.2	5.6	0.4	0.8	0.5 N.S.

* $p. < 0.05$. † $p < 0.01$.

is Reasoning which old schizophrenics evidently find easier.) These data, however, present one apparently discrepant finding. Older schizophrenics show much less general deterioration than young schizophrenics when compared with normals of the same age. None of the other studies discussed suggested that this would be the case. There is usually a tendency for deterioration to be progressive with uninterrupted psychosis. It is, of course, conceivable that the older schizophrenics were unrepresentative in that they all had atypical illnesses of short duration starting late in life. However this seems unlikely. This is apparently the oldest schizophrenic group reported in the literature, and if the finding is reliable, it would appear that after about age 45, schizophrenic deterioration slows down markedly so that the normal deterioration due to age begins to narrow the gap between schizophrenics and normals.

Summary and Conclusions

While unequivocal studies are lacking, there is no evidence that any psychiatric group finds any particular

available for all the different types of problem described, and only those for which abnormal data exist will be discussed.

(a) Perceptual Tests

Many cognitive tests merely require the subject to discriminate between simple visual patterns. Nevertheless they are usually correlated fairly highly with other cognitive measures. It is clear that cognition and perception cannot be separated completely. As Combs (1952) has pointed out, before we can think about any problem we must be able to perceive the elements of the problem. If we cannot differentiate these, we will be unable to solve it at all. Combs argues that: "The effectiveness of . . . behavior will necessarily be a function of the adequacy of . . . perceptions." He points out that people who have never learned to differentiate within certain perceptual fields through lack of exposure to them will never develop intelligence in this field.

Certainly perception is necessary to obtain the manipulanda of a problem, and it is not surprising

that individual differences in the ability to discriminate are related to problem-solving ability. (Some studies even report a correlation between speed of discrimination of patterns of dots tachistoscopically presented, and vocabulary, cf. Kretch and Calvin, 1953; De Soto and Leibowitz, 1956; Pickwel, 1957.)

Abnormalities in perception have often been demonstrated in psychiatric groups and while this subject will be dealt with elsewhere, a few salient findings will be mentioned here.

Combs and Taylor (1952) attempted to demonstrate that anxiety (produced by "threat" or "stress") restricts the range of perception. A group of normal subjects were given the task of "coding" sentences. In one group neutral sentences were used, while in the other group the sentences contained a threat (e.g., "I said that my mother is a dirty whore," "Something is wrong with my sex organ"). Verbal threats by the examiner were also used in the second part of the experiment. As predicted, the "threat" sentences produced significantly more errors and took significantly longer to code.

The Bender-Gestalt test (Bender, 1938) merely requires the subject to copy a simple line drawing. Pascal and Suttell (1951) demonstrated that errors in reproduction, scored relatively objectively, differentiated between a large group of mainly neurotic out-patients, and a large group of mainly psychotic in-patients. The in-patient group made inferior reproductions. Gobetz (1953), testing one hundred and eight neurotics and two hundred and eighty-five normals, found that the neurotics reproduced the Bender-Gestalt drawings as accurately as normals. Lonstein (1954) found that forty-seven psychotic patients were significantly worse at reproducing the Bender-Gestalt drawings than forty-nine non-psychotics.

Niebiehr and Cohen (1956) tested ten normals, ten acute schizophrenics and ten chronic schizophrenics on the Bender-Gestalt test. Normals were best, acute schizophrenics worse, and chronic schizophrenics worst of all. These authors demonstrated that motor abnormalities alone could not explain the results, as they found a similar differentiation using a multiple-choice form of the test in which the subjects merely had to select the most accurate of six reproductions. Suttell and Pascal (1952) found that the errors in reproduction made by schizophrenics were quite unlike those made by children on this test.

Brengelmann in a series of studies (Brengelmann, 1953; Brengelmann and Pinillos, 1953) has demonstrated that abnormal groups are significantly poorer at recognizing pictures or objects presented tachistoscopically. Neurotics require significantly longer exposures than normals, and psychotics significantly longer exposures than neurotics. Alice Angyal (1948, 1952) found that schizophrenics make more errors in

reproducing patterns of letters presented tachistoscopically than normals. Granick (1955) found evidence that neurotic children score less well than normal children in tests involving visual discrimination.

There seems to be considerable evidence then, that many psychotic patients are abnormally poor at tasks involving visual discrimination. The evidence for neurotics is less clear-cut. Brengelmann's and Granick's results suggest that some neurotics may also be poor at visual discrimination, and Combs and Taylor's findings suggest that this might be particularly related to high anxiety.

Penrose's (1945) results demonstrate that schizophrenics are below average in performing tests which merely involve visual discrimination (see Table VI.13, Tool recognition test). It is probable then, that the poor performance of psychotics on many performance tests involving visual material is partly due in some cases to visual perceptual abnormalities. The nature and possible causes of these will not be dealt with in this chapter.

There is less evidence for perceptual abnormalities in other modalities. One study (Trussell, 1939) even suggests that some schizophrenics may be better at auditory discrimination. A group of thirty-two schizophrenics were given the "verbal summator" test (a gramophone record of unintelligible speech played softly). Significantly more schizophrenics than normals when asked what the record said, gave a "meaningless" response. While there is some objective evidence (Wallace, 1956; De La Garza and Worchel, 1956) for some degree of disorientation in time among schizophrenics, it is not known what perceptual modality is involved.

These studies are all less than satisfactory, since perceptual abnormalities are merely related to broad diagnostic labels. It would be extremely interesting to know which psychotics (and which neurotics) suffer from perceptual abnormalities. It is always tempting to hypothesize that severe perceptual abnormalities will be found among those psychotics who suffer from hallucinations, and to expect these to occur in the same modalities. It is also conceivable that perceptual abnormalities, when found in neurotics, will be related to feelings of "unreality."

(b) Tests of Fluency

One of the earliest extensive investigations of fluency in abnormal subjects is reported by Studman (1935), who administered the eight fluency tests defining Spearman's "f" factor to a group of patients. Most fluent were nine manics who were well above average. Nineteen delusional patients, fifteen manic-depressives, seven anxiety neurotics and sixteen epileptics obtained average scores. Three groups were well below average in fluency, obtaining very similar scores: eighteen

cases of *dementia praecox*, twenty-one melancholics and twenty hysterics.

Eysenck (1947), also using a group of fluency tests, found no significant differences between much larger groups of hysterics and dysthymics, and thus did not support this aspect of Studman's results. On the other hand, he found neurotics to be less fluent than normals, and a fluency test had a moderate saturation on a factor of neuroticism (Eysenck, *The Dimensions of Personality*, p. 256, 1947). In a later study Eysenck (1952) reports that a single fluency test (naming animals) differentiated between neurotics and psychotics, and had a fairly high loading on a factor defined by a number of tests differentiating these groups which he called "psychoticism." Psychotics were less fluent than neurotics.

Sybil Eysenck (1955), using three tests of fluency, found that, compared with one hundred and twenty-three normals, fifty-five neurotics had slightly lower scores, and fifty-five psychotics had much lower scores still. The overall results (*F* ratio) were significant at the 0.1 per cent level for each test. Within the psychotic groups, however, schizophrenics and depressives obtained nearly identical scores.

The evidence, then, is fairly consistent that neurotics are slightly below average in fluency, while both schizophrenics and depressives are considerably below average. Studman's early finding that nine manics were above average has not been repeated, as later studies did not investigate this group.

It is probable that fluency is not an important determinant of the score on most cognitive tests, so that it is difficult to account for general deterioration on other tests in these terms. What aspect of symptomatology is related to fluency is not known, although it could conceivably be related to the general level of activity of mental patients.

(c) Tests Involving Inductive Reasoning

In the last section it was pointed out that in Penrose's (1945) study, schizophrenics obtained their worst scores on two tests which apparently involve inductive generalization. (Picture completion and Pictorial absurdities, see Table VI.13.) These results are consistent with other reported findings.

Hausmann (1933) selected a group of one hundred and six patients (mainly psychotic) all of whom complained of being unable to think. He found that on two tests of absurdities and incongruities (one pictorial, one written), they obtained much lower scores than thirty-five school children and eighteen student nurses. Hunt (1935) showed that twenty-five schizophrenics were worse at detecting absurdities in a narrative than were eighteen organics, although the schizophrenics were better on other tests.

Hanfmann (1939a, 1939b) gave the Healy Pictorial

Completion Test (Healy, 1921) to sixty-two schizophrenics, seventy normals and seventeen organics. The schizophrenics were much poorer than the normals. The piece selected to complete the picture was often incongruous with the action implied, and sometimes introduced a physical impossibility. Some pieces were selected as merely "symbolizing" the picture, and some solutions were quite incomprehensible. Normals made no absurd placements at all, while two-thirds of the schizophrenic group made one or more absurd placements.

Most of the studies on the ability to perform inductive reasoning utilize "sorting" tests and will be discussed later. Altogether there is considerable evidence that, for whatever reason, schizophrenics do especially poorly at tests which require inductive reasoning or the formation of an abstract generalization. Data for affective disorders are lacking.

Since inductive reasoning is required to some extent in a number of cognitive tests (e.g. Thurstone's letter series items), this disability may well be a factor in the impaired performance of some psychotics on these tests.

(d) Tests Involving Deductive Reasoning

Most problem arithmetic tests involve deductive reasoning almost exclusively. While there was some suggestion that Wechsler-Bellevue subtests involving "number" were low among schizophrenics it was pointed out that other studies suggest that schizophrenics are *not* especially bad at arithmetic problems. Indeed Malamud and Palmer (1938) found that the Binet items performed best by schizophrenics were vocabulary, information and problem arithmetic items. Shakow (1946) also found arithmetical reasoning least impaired in schizophrenics.

The most satisfactory deductive reasoning test was used in a study by O'Connor (1952). She gave a syllogisms test to a group of students, and even after general intelligence had been partialled out, obtained a significant correlation (-0.368) between deductive reasoning ability and "ethnocentrism" (California "E" scale). Intolerant people obtained low reasoning scores.

Thus, while studies are few, there is no evidence that any abnormal group is particularly bad at deductive reasoning as such, although this specific ability may have other important correlates. The observed differences in general level cannot be explained in terms of a defect of this sort.

(e) Tests of Originality

While Guilford believes "originality" is an important cognitive factor, and a number of measures have been developed and shown to correlate fairly highly (Guilford *et al.*, 1951; Barron, 1955), there are no

studies with abnormal subjects using these tests. There is, however, a large volume of data derived from studies using the "word association" technique, which provides a situation in some ways analogous to some of Guilford's tests.

No attempt will be made here to review the literature on word association. However, one finding is frequently reported (cf. Bell, 1948; Rapaport *et al.*, 1945). Schizophrenics tend to give highly original or unusual responses to the word-association test. Normal people behave as if they must keep within certain boundaries which are not usually mentioned in the instructions. In some ways schizophrenics are more "flexible," not assuming so many prohibitions. For example, Sybil Eysenck (1955) tested one hundred and thirty-five normals, fifty-five neurotics and fifty-five psychotics. She found that the psychotics: (a) repeated the stimulus word more frequently, (b) gave multiple responses more frequently, (c) perseverated the same response more frequently, (d) gave synonyms more frequently, (e) gave "cause-effect" responses more frequently, (f) more frequently had fewer than 10 per cent "popular" responses, and (g) gave fewer responses agreeing with the majority. All these differences were highly significant in differentiating the three groups, and in every case the neurotics were much more like the normals than the psychotics.

It is interesting that Smith and Raygor (1956) were able to produce unusual responses to a word association test in normals by "satiating" them on each stimulus word beforehand. This was done by having them fixate, and write the stimulus words before doing the test. Presumably the more common (stronger) "associations" become satiated, allowing the weaker $S^H R$ links to become prepotent. This could provide a rationale for the growing practice in advertising of having "brain storming" sessions which last for many hours when there is a strong need for fresh or original ideas.

Quite possibly many psychotics would obtain relatively high scores on measures of originality. It is doubtful whether originality is an important determinant of the score on many cognitive tests. It is reasonable, however, to expect that it might be an asset in solving some "sorting" tests of inductive reasoning. This finding therefore is at first sight somewhat discrepant with the hypothesis that schizophrenics are especially poor at "induction."

Summary and Conclusions

1. There is considerable evidence that many psychotic patients have visual perceptual abnormalities which make them inferior at performing tests of visual discrimination. There is, however, no evidence for differences between schizophrenics and the affective

disorders. Some neurotics may also have perceptual disabilities which might be related to anxiety. Perceptual abnormalities could partly account for the relatively poor scores obtained by psychotics on some performance tests of general intelligence. It is tempting also to relate them to the tendency in psychotics to develop hallucinations, and to feelings of unreality in neurotics, although no studies appear to have been done.

2. Neurotics are less fluent than normals and psychotics are less fluent than neurotics. Manics may be an exception in being more fluent than normal. It is difficult to account for many cognitive differences in terms of differences in fluency. It is conceivable that fluency might be related to the general level of activity although specific studies are lacking.

3. Schizophrenics appear to be especially bad at solving problems which require induction or the formation of abstract generalizations. This could contribute to their general cognitive disability.

4. There is no evidence that any abnormal groups have a specific disability for tests involving deductive reasoning.

5. There is some evidence that schizophrenics may be considerably above average in originality or the tendency to give unusual responses. It is doubtful whether this ability is important for the solution of many cognitive tests however.

COGNITIVE PROCESSES

(a) Speed

Furneaux has demonstrated that speed of problem-solving is one of the most important determinants of score, even on untimed tests. There is some evidence, however, that in normal people problem-solving speed is related to the type and content of the problem. For example, Rimoldi (1951) factor-analysed a large number of tests of "personal tempo," including speeded cognitive tests (Thurstone's P.M.A.). While no "pure" (i.e. error-free) speed measures were used, Rimoldi concluded that speed is not unitary. He suggested that speed of cognition, motor speed and perceptual speed are relatively independent. Even within the P.M.A. tests, speed of performing reasoning and space tests was relatively unrelated to speed of performing number and verbal tests.

Harriet Babcock (1930, 1933, 1941*a*) was the first psychologist to hypothesize that abnormal slowness among psychotics can account almost entirely for the general intellectual deterioration they demonstrate. Indeed, she believed that much of their general behaviour (unsociability, etc.) could be explained in terms of this relatively specific cognitive defect. As has been mentioned, Babcock demonstrated that a

large number of very simple motor and mental speed tests differentiate well between normals and psychotics, and that psychotics obtain their lowest scores on such tests. Babcock used such measures almost exclusively to assess present level of efficiency in her test of deterioration. The data concerning the efficiency index have been discussed.

Shapiro and Nelson (1955) report an extensive investigation into Babcock's hypothesis. Twenty normals, twenty schizophrenics, twenty manic-depressives and twenty organics matched for age were given the Babcock test and other measures of speed (the Nufferno test). The authors predicted that if Babcock's theory were correct: "(a) Speed tests should significantly differentiate psychiatric groups and normals. (b) Speed tests should correlate negatively and significantly with degree of illness and prognosis. (c) Intercorrelations of the Babcock error-free speed tests should be consistent with the presence of a general factor of speed. Also, the Babcock speed tests should correlate significantly with other tests of speed." These predictions were nearly all verified. Normals were fastest on all the speed tests. Neurotics were usually slightly but significantly slower. Acute schizophrenics were slower than neurotics, manic-depressives slower still, and chronic schizophrenics and organics slowest of all. All the Babcock speed tests correlated with degree of illness and prognosis (of sixty-four correlations, only twelve were not significant).

The intercorrelations of the tests produced interesting results. As one might expect from Rimoldi's study, within the normal group the correlations were all low, "contraindicating the presence of one important general speed factor in normals." Within the three main abnormal groups the correlations were relatively high. When these were factor-analysed (Nelson, 1953) two relatively independent factors could explain the correlations. One was made up of mental speed tests, and the other was made up of motor speed tests. There is evidence, then, that in abnormal groups, motor retardation is relatively independent of slowness of reasoning. The higher intercorrelations between the tests in abnormals is due to the fact that they have a much wider range of speed scores. Normal subjects are relatively homogeneous on these measures.

Shapiro and Nelson's last test of Babcock's hypothesis was to match two groups (normal and abnormal) for psychomotor speed. These groups did not differ significantly on the Nufferno level test (an untimed letter series test) or on vocabulary. Again this was consistent with the theory that slowness is sufficient to account for differences in general level between normal and abnormal groups.

Campbell (1957) and Kessell (1955) also found that

several Babcock speed subtests differentiated well between normals and psychotics, thus confirming earlier results.

Many other studies have investigated speed of performing cognitive tests in abnormal groups. For example, Hausmann (1933) demonstrated that one hundred and six psychotic patients, all of whom complained of being unable to think, were slow on the substitution test of the Army Alpha. Senf, Huston and Shakow (1955) tested twenty-four chronic schizophrenics, twenty-two early schizophrenics, twenty-one depressives and twenty-one neurotics on the Army Alpha test with a ninety-second time limit, and on the same test with no time limit. When no time limit was given, there were no significant differences between the groups. On the timed test, the three psychotic groups were significantly worse than the neurotics, although there were no differences between the psychotic groups.

Eysenck (1947) found no tendency for five hundred neurotic soldiers to perform an untimed test any better than a timed test.

Foulds (1951) using a modified form of the Porteus Maze Test (allowing subjects to correct errors) found that both in "starting time" and total tracing time, introverted neurotics (anxiety states, reactive depressives and obsessionals) were significantly slower than extraverted neurotics (psychopaths and hysterics). Foulds (1952) also found that psychotic depressive patients were slow on the same measures. Kessell (1955) and Campbell (1957), repeating Foulds's work found that schizophrenics and depressives were significantly slower than normals in tracing time, although the two psychotic groups did not differ. "Starting time" results were less clear-cut, but the psychotic groups were always slower.

Unfortunately none of the studies so far mentioned are entirely conclusive. As Furneaux points out, to obtain time measures uninfluenced by other factors it is necessary to time every test item and to exclude the time taken for wrong items. Even Babcock's very simple error-free speed tests have been shown to produce errors in psychotic groups (Kessell, 1955).

Fortunately, there are a number of studies which make use of the Nufferno speed tests (cf. Furneaux). The results are very similar. Ogilvie (1954) compared a group of normal and schizophrenic subjects matched for age and general level (using Wechsler-Bellevue tests). The schizophrenics were significantly slower. Broadhurst (1957) obtained similar results using both schizophrenics and depressives.

Shapiro and Nelson (1955) report Nufferno speed and level test scores for groups of normal and abnormal subjects matched for age (mean age = 41, range = 20 - 50). Their results are summarized in Table VI.15.

TABLE VI.15
NUFFERNO SPEED AND LEVEL SCORES FOR DIFFERENT ABNORMAL GROUPS
(After Shapiro and Nelson)

Test	Number of cases	Normals	Acute schizophrénics	Chronic schizophrénics	Manic-depressives	Organics	Neurotics	F ratio	Significance
		20	6	14	20	20	20		
"Nufferno" level test	Mean . .	10.30	8.50	4.64	5.90	4.46	8.95	4.98	*

	Range . .	0.73-1.28	0.88-1.27	0.92-1.48	0.76-1.76	0.87-1.59	0.62-1.38		

* Significant at the 0.001 level

† Significant at the 0.05 level

‡ Not significant.

Eysenck reports an investigation in which one hundred and six normal male soldiers were compared with twenty psychotics and twenty neurotics (Eysenck *et al.*, 1957). The groups were not matched, although they are of similar age. The results are given in Table VI.16.

Although the speed-test score differentiates significantly, there are no significant differences between the groups on the Nufferno level test.

the groups significantly. The neurotics tended to be similar to the normals, or a trifle slower, while the two psychotic groups were both very much slower, there being little difference between the schizophrenics and the depressives. All the tests were intercorrelated, and factor-analysed for the combined group of subjects. A factor which was labelled "retardation" was obtained, on which nearly all the speed tests had high loadings. Factor scores were calculated and it was

TABLE VI.16
NUFFERNO SPEED AND LEVEL TEST SCORES IN NEUROTICS, PSYCHOTICS AND NORMALS
(After Eysenck)

Score		Control	Neurotic	Psychotic	Significance
Level	Mean	5.313	5.975	5.175	$F = 1.052$
	Variance	3.186	6.050	6.335	Not. sig.
Speed (mean log time)	Mean	0.961	0.969	1.166	$F = 15.042$
	Variance	0.020	0.029	0.041	Sig. at 0.1 per cent

Payne and Hewlett (to be published) administered a large battery of tests to carefully matched groups of twenty normals, twenty neurotics, twenty depressives and twenty schizophrenics. These tests included simple measures of mental and motor slowness (from Babcock's battery), the Nufferno Speed tests, tests of perceptual speed, tests of "overinclusive" thought disorder, tests of "concreteness" of thinking, and other measures. The results were consistent with earlier studies, in that the speed tests differentiated

shown that this factor significantly differentiated between the combined neurotic and normal groups, and the combined psychotic group. However, the schizophrenics were not significantly different from the depressives, both being equally retarded. In contrast to Nelson's (1953) finding, there was no tendency for motor and mental speed tests to be uncorrelated. Motor, mental and perceptual speed tests all differentiated the groups equally well, and had roughly equal loadings on the "retardation"

factor. This factor of general retardation was correlated -0.38 with a factor labelled "overinclusive thinking." This was consistent with the hypothesis that abnormal slowness in schizophrenics is partly the result of this type of thought disorder. However, it was demonstrated that "overinclusion" could not entirely account for all the retardation shown by the schizophrenic group, and could account for none of the retardation shown by the depressives. It was concluded that in a psychotic group, abnormal slowness has at least two causes.

These studies yield consistent results. It is clear that even when the groups are matched for general level, psychotics tend to be significantly slower at problem-solving than neurotics and normals. There is apparently no difference in problem-solving speed between schizophrenics and manic-depressives. Even when manics as a group are treated separately, they obtain a similar mean score (Nelson, 1953) to the other psychotic groups. Early psychotic groups, however, are considerably faster (very near to normal), while chronic groups are considerably slower.

It is interesting that pure measures of speed of problem-solving (Nufferno speed tests) differentiate the groups less well than the Babcock tests of motor and mental speed. This may be because these tests also measure a third abnormality, "error," the effect of which will be discussed later. Motor speed will not be discussed further here, as it is dealt with elsewhere (see Chapter 2).

There is a considerable amount of overlap between psychotic and normal groups in problem-solving speed. In all the studies quoted, a proportion of psychotics obtain better than average scores. Indeed, Shapiro and Nelson's acute schizophrenics are not significantly slower than normals on one measure. It is thus fair to say that this abnormality is by no means uniformly present in psychosis. Ogilvie (1954) examined the discrepancy between speed and level in his schizophrenic group, and almost all his patients had speed percentile scores below their level percentile scores. This suggests that some "slowing down" of mental speed may be found in most psychotics, but there are very large individual differences in the amount of slowness produced.

On average, neurotics are a trifle slower than normals at problem-solving, but not as slow as psychotics. The neurotic range is apparently such that some neurotics get just as good (fast) scores as the best normals. However a small proportion are somewhat below the normal range. There are, however, significant differences between neurotic groups. Foulds (1951) found extraverted neurotics to be faster than introverted neurotics.

Foulds (1956) also followed up Himmelweit's (1945) finding that dysthymic neurotics get higher

Mill Hill Vocabulary scores, while hysterics get higher Matrices scores. Foulds pointed out that in Himmelweit's study, a timed (twenty minute) version of the Matrices was used. When Foulds gave the Matrices test both timed and untimed, he found that, although hysterics were better at the timed test than dysthymics (thus producing a discrepancy in favour of the Matrices test) this was *not* true for the untimed test. Without a time limit, dysthymics considerably improve their scores, so that the Vocabulary-Matrices discrepancy no longer differentiates the groups. This study suggests clearly that extraverted neurotics are *faster* than introverted neurotics at problem-solving.

Furneaux has found similar results in normal students. If the Guilford-Martin "R" scale is used to measure extraversion-introversion in normals, and the "D" and "C" scales are used to measure neuroticism, it is possible to compare subjects falling in the four "quadrants." It is the neurotic-extraverts who are fastest. Intermediate are the neurotic-introverts. The other two groups, normal-introverts and normal-extraverts are slowest, there being no difference between them. This does not coincide with the finding that neurotic patients are a trifle *slower* than normals on average. However the normal student group is relatively homogeneous with respect to neuroticism, and presumably only severely neurotic individuals have speed scores below (slower than) the normal range. The implication is that there is a curvilinear relationship between neuroticism and speed, people who are moderately neurotic being faster than the two extreme groups. This will be discussed further, later.

Clearly a combination of mental and motor slowness can account for much of the data discussed in earlier sections. The relative positions of different diagnostic groups on the Babcock efficiency index can be entirely accounted for in these terms, as Shapiro and Nelson have demonstrated. Mental and motor slowness can also account for many of the differences noted in subtest performance. On the Wechsler-Bellevue, Digit Symbol was the lowest subtest score in schizophrenics and among the lowest in other psychotic groups (see Table VI.12). This is the "purest" measure of speed in the Wechsler scale. The low Arithmetic score among schizophrenics may also be due to the fact that this is the only timed Wechsler Verbal subtest. The generally low level of psychotic groups on the P.M.A. tests (see Table VI.14) and the Canadian Army "M" tests (see Table VI.13) could also be due partly to the fact that these tests are timed. Conversely the tests *least* affected by speed (Wechsler Vocabulary, Information) are always highest in psychotic groups *unless* a time limit is imposed, as in the case of the Verbal meaning subtest of the P.M.A. (see Table VI.14). One fact, however, which *cannot* be explained by differences in speed is the fact that

introverted neurotics have a higher general level than extraverted neurotics.

Since by no means all psychotic patients are extremely slow, it would be interesting to discover whether or not slowness is related to any specific symptom. A study by Wittenborn and Holzberg throws some light on this problem. Holzberg (1951a) gave Wittenborn's symptom rating scales (Wittenborn, 1951; Wittenborn and Holzberg, 1951b) and the Wechsler-Bellevue test to a mixed group of seventy-nine psychotics and neurotics. While rating scales of this sort have been criticized on the grounds that inconsistent results have been reported perhaps due to "rater-bias" (Trouton and Maxwell, 1956; Lorr, Jenkins and O'Connor, 1955), this study is at least suggestive. All nine "syndrome scores" were correlated with the Wechsler subtests. Very few correlations were significant. However, the Digit symbol subtest (the only relatively pure speed measure) correlated — 0.251 with the Paranoid Schizophrenia scale, and — 0.288 with the Paranoid Condition scale. The symptoms common to these two scales are persecutory ideas and delusions. It is conceivable that psychotics (both schizophrenics and manic-depressives) with these symptoms tend to be slow, while others do not. If this were accepted, however, we could not account for severe general deterioration purely in terms of slowness, since we have seen that patients with paranoid delusions probably do *not* deteriorate severely.

Harris and Metcalfe (1956) report a study of the symptom of "inappropriate affect" in psychotic patients. A group of forty schizophrenic patients were carefully rated for this symptom, and divided into three groups displaying "grossly flat" affect, "moderately flat" affect and "no flatness." These patients were given a battery of tests including the Wechsler-Bellevue, the Nufferno speed and level tests, analogies tests, sorting tests, proverbs tests, an "essential differences" test and an "absurdities" test. The results clearly suggested that *only* the tests involving mental speed (the Nufferno and the Wechsler—on account of the timed subtests) differentiated significantly. In each case the patients with "flat affect" were much slower. This symptom was also found to correspond highly with the general prognosis. The results confirm Shapiro and Nelson's finding that slowness is related to a poor prognosis. There was some tendency for inappropriate affect also to be related to severity of illness, and it is not certain that this factor alone might not have produced some of the differences in speed which were found.

Cognitive slowness, then, seems to be related to at least three variables. Extraverts tend to be fast, and introverts tend to be slow. There may well be a curvilinear relationship between speed and neuroticism.

Thirdly, there is a tendency for psychotics to be very slow. Since neuroticism and introversion-extraversion are unrelated, and since neither of these variables, probably, has any relationship with psychosis (Eysenck, 1952), it is highly likely that slowness can have several quite unrelated causes. Indeed this is highly probable *a priori*.

It is possible to conceive of problem-solving as some cerebral "search" process, where more difficult (complex) problems involve more cerebral "units," which have to be examined in all their permutations and combinations. Slowness could occur for a number of reasons. First of all, there could be important individual differences in the speed of the search process itself, very slow people for some reason or other having very slow "searching mechanisms." Slowness could also occur if, for some reason or other, the search process were interrupted, through distraction or blocking. Slowness could occur in some people if they found it necessary to repeat it a second time ("obsessional" checking). Finally, slowness could occur in some people if they misinterpreted problems in such a way that they made them needlessly complicated. Such people might consider data which normal people would regard as irrelevant, and thus considerably extend the length of the search process, since many more units would be involved, and many more permutations and combinations possible.

Various attempts have been made to account for abnormal slowness in different disorders. Most of these explanations will be treated in later sections. Two lines of approach, however, will be mentioned here.

Dispensa (1938) administered Thurstone's Psychological Test for college entrance to a large number of college women. Measures of basal metabolism were also taken. Three groups of women were obtained, seventy-eight with normal thyroid function, thirty-five with an overactive thyroid, and forty-one with an underactive thyroid. There was a significant tendency for the hyperactive thyroid group to be brighter, and the hypoactive thyroid group to be duller than the normal group. In fact even *within* the groups, measures of thyroid activity correlated significantly with intelligence. In view of other known effects of the thyroid, it is very tempting to attribute these differences to differences in mental speed. One might even suggest that the speed of the search process itself might ultimately be found to be partly a function of some such basic metabolic process.

The other line of investigation was entirely different. A study by Layman (1940) suggested that Sodium Amytal significantly increased mental speed in schizophrenics (as measured on form board tests). This could have accounted for the findings of Mainord (1953) and Senf *et al.* (1955) that amytal apparently

increased the intellectual level of schizophrenics. Ogilvie (1954) and Broadhurst (1957) pointed out that these studies were relatively uncontrolled, as no *placebo* group had been tested. When Ogilvie repeated Layman's study *without* a *placebo* group, he found that amyltal produced a significant speeding up in schizophrenics on the Nufferno tests. However when Ogilvie (1954) and Broadhurst (1957) later used a careful design in which a *placebo* group was tested, and the experimenter did not know whether the patient had been given amyltal or *placebo*, no differences attributable to the drug were obtained. (Both groups, however, showed a considerable practice effect on retest.) These experiments do not "disprove" the earlier results. They merely suggest that they were not due to amyltal. It is conceivable that the examiner's knowledge that the drug has been given and his (and the patient's) "faith" that it will produce striking results in some way produces an increased drive on the part of the patient. The evidence to be discussed later makes this at least a plausible hypothesis.

This line of inquiry has led to the interesting discovery by Campbell (1957) that by and large the slower the initial level, the greater the effect of subsequent practice in improving the speed of psychotic patients, at least on the Porteus Maze test. This is discussed elsewhere (by Jones) and will not be elaborated here.

Summary and Conclusions

1. Some psychotics are abnormally slow at performing mental and motor tests.
2. There is no evidence that schizophrenics, manics or depressives on average are differentiated by mental or motor speed tests.
3. Early psychotics are probably considerably faster, and not much slower than normals, while chronic psychotics are considerably slower on both types of speed tests.
4. In the psychotic groups, there may be a tendency for slowness to be associated with delusions of persecution, "inappropriate affect," and severe depression.
5. Motor and mental slowness can account for a good deal of the general deterioration noted in different groups, and can partly explain the subtest order produced on many tests of general intelligence.
6. There is probably a curvilinear relationship between cognitive speed and neuroticism, moderately neurotic individuals being faster than extremely stable or extremely neurotic individuals.
7. Extraverts tend to be faster than introverts on cognitive speed measures.
8. Cognitive slowness can probably be produced in a number of different ways, and different abnormal groups may be slow for quite different reasons.

(b) Persistence

Furneaux has demonstrated that persistence is another important determinant of score on cognitive tests, and that it becomes increasingly important when the tests are given with no time limit. It is obvious that individuals abnormally lacking in persistence would obtain reduced scores on most cognitive tests.

Factorial studies in normals (Ryans, 1938*a*, 1938*b*; Thornton, 1939; Rethlingschafer, 1942; Kremer, 1942; MacArthur, 1951) suggest that there may be two fairly well defined and relatively independent types of persistence, "ideational" and "physical." The former refers to the amount of time which is spent on very difficult or insoluble intellectual problems, the latter to the length of time people are prepared to submit to boring, fatiguing or uncomfortable physical tasks.

Unfortunately all the work with abnormal subjects appears to refer to tests of physical persistence. A series of studies (Eysenck, 1947, 1952; Sybil Eysenck, 1955) suggests that neurotics as a group may be less persistent than normals, and that extraverted neurotics are less persistent than introverted neurotics. While psychotics tend to be less persistent on some physical tests, the data are inconsistent. These findings would not necessarily apply to measures of intellectual persistence however.

One reason for the lack of data for intellectual persistence measures in abnormal groups may be the difficulties involved in collecting it. For example, Payne, Matussek and George (1959) recently attempted to measure the persistence of mental patients by using an insoluble problem. The problem at first sight looked simple enough, and the patients found it very interesting. This and other tests were given individually and all patients were warned not to discuss the tests with anybody else. After several patients had taken the test, however, the next refused to try it, saying it was impossible. He said that all the patients on his ward had spent half the night trying to do it, and they came to the conclusion that it was not possible. The test had to be abandoned.

If direct evidence is lacking, some inferences are possible however. In the study reported by Eysenck and summarized in Table VI.16 (Eysenck *et al.*, 1957) it was found that twenty psychotics were not significantly worse at performing the Nufferno level test than one hundred and six normals of similar age. The groups had not otherwise been matched, and the psychotics were significantly slower than the normals. Furneaux has shown that the score on the level test is determined almost entirely by three variables, speed, error and persistence. As will be mentioned later, there were no significant differences in "error" between the groups, although the psychotics made slightly *more* errors. In order to compensate for their

slowness, therefore, it is clear that the psychotics must have been considerably more persistent than the normals, to have attained a similar level score.

Unfortunately similar deductions cannot be made from the data on neurotics. As it will be seen, however, other factors could account for the test performance of neurotics, and there is no need to postulate abnormally low persistence at intellectual tasks.

There is some slight evidence that introverted neurotics may be more persistent on cognitive tests than extraverted neurotics. Foulds (1956) demonstrated that on the untimed Matrices test, extraverted neurotics tend to do better at the beginning of the test and worse at the end of the test, while introverted neurotics tend to do better at the end of the test.

Summary and Conclusions

1. Early psychotic patients are probably more persistent than normals at cognitive tests, probably to compensate for their slowness.

2. There is no evidence about intellectual persistence in neurotics, but there is no reason to believe them abnormal in this respect.

3. There is some slight evidence that introverts may be more persistent than extraverts on cognitive tests.

(c) Error

Giving a wrong answer to a cognitive test in the mistaken belief that it is correct, is the most important single determinant of the score on many tests, especially untimed tests (cf. Furneaux). However, no satisfactory explanation of error has ever been advanced. Theories of problem-solving attempt to describe many stages in the process. Whether "thinking" is regarded as internalized trial and error learning, a search process or anything else, it is necessary to explain how the organism "knows" when the correct answer has been obtained. How is the answer "checked" when thought is completed, and how does this checking mechanism itself come to possess a criterion of the correct answer? Until this is explained, it is difficult to account for error, which is presumably some failure in the checking process.

There are obviously important individual differences in accuracy. Unfortunately few cognitive tests provide a measure of accuracy which is uncontaminated by other factors (abandonment, for example). The results are therefore ambiguous, and there are surprisingly few conclusive results for abnormal subjects.

One interesting series of studies relates to the Porteus Maze Test (Porteus, 1923). Poull and Montgomery (1929) gave this test to thirty-two girls and forty-two boys with "conduct disorder," and thirty-four girls and forty-seven boys who were well

adjusted. The well-adjusted children obtained better Porteus Maze scores than Binet scores. The poorly-adjusted children obtained worse Maze scores than Binet scores. However the same groups showed no difference between Binet and Healy Completion Test II scores. This study was repeated in 1932 by Karpelles on one hundred and eighty-five normal boys and girls and one hundred and eighty-five maladjusted children who were "behaviour problems." Again there was a highly significant difference between the groups. The adjusted group had, on average, a higher Porteus I.Q. than Binet I.Q., while the behaviour problem group showed no differences. These studies suggest that the Maze test is not well standardized. However there is a consistent tendency for delinquent and problem children to get low Porteus Maze scores.

The reason for this difference soon became clear. The delinquent groups obtained low scores because they made more errors. However the errors were of a specific sort. The instructions clearly forbid going down blind alleys and retracing one's path, cutting corners, crossing lines, lifting one's pencil, and so on, while tracing through the mazes. The delinquent groups tended to be "impulsive" and disobeyed these instructions. This accounted for their poor performance when the test was administered and scored normally. Porteus (1942) produced a special scoring system, counting up errors of this sort, which he called the Qualitative (Q) score. He demonstrated that this score was even better for separating delinquent from normal children. This finding has often been repeated. It was repeated on children by Wright (1944), Doctor and Winder (1954), and Fooks and Thomas (1957). The Q score was also found to differentiate between adult delinquents and normal adults (Porteus, 1942; Purcell, 1956).

It is not surprising to find that delinquents or psychopaths are more impulsive and disobedient, even in the context of a simple test. Eysenck (1947, 1952) found such traits related to the personality dimension introversion-extraversion, and Hildebrand (1953) demonstrated that psychopaths were more extraverted than any other neurotic group. Hildebrand also demonstrated that the Porteus Maze Q score is a good measure of introversion-extraversion.

This research suggests that extraverts tend to make more errors than introverts probably because of such personality traits as impulsiveness and carelessness. That this is not confined to the Porteus Maze test is suggested by Furneaux, who demonstrated that the error score on the Nufferno speed and level tests is correlated with extraversion as measured by the Guilford-Martin R scale in normal students. Again, extraverts make more errors.

This fact is consistent with some of the data discussed in the first section. It was pointed out that I.Q.

appears to be related to introversion-extraversion within neurotic groups, the extraverts getting lower scores. It was also pointed out that delinquents usually get even lower I.Q. scores. If delinquents (psychopaths) are the most extraverted group of all, the correlation between error and extraversion can to some extent explain these differences.

In some ways, error through impulsiveness or carelessness could be regarded as "non-cognitive." That is, the assumption is that careless individuals could be made to reduce their errors if they could be made to change their attitude towards the test. Presumably these errors are *not* due to some basic abnormality of the checking process. If this is accepted, it is possible to make errors for more than one reason, since it is possible to imagine individuals whose checking mechanism is inaccurate, and who make a higher proportion of errors unavoidably. There is some evidence that this might be true of some psychotics.

Kessell (1955) found that more seriously ill psychotics made a substantial number of errors on the simple Babcock error free speed tests. Since Babcock's data suggest that normals do not make errors, and since this was the reason for selecting the tests, it is reasonable to conclude that psychotics are abnormal in this respect.

Eysenck examined the error scores of twenty psychotics on the Nuffern speed test (Eysenck *et al.*, 1957). The normal controls ($N = 106$) had a mean error score of 3.070 (variance = 8.490), twenty neurotics had a mean error score of 2.600 (variance = 8.884) and twenty psychotics had a mean error score of 4.450 (variance = 20.997). While psychotics made more errors, the difference was not significant ($F = 1.707$). However, Furneaux has combined these data with the data for schizophrenics collected by Ogilvie (1954) and Broadhurst (1957). He found a distinct tendency in all these studies for schizophrenics to make more errors than normals working at the same speed. Furthermore, if differences in variance are allowed for, the correlation between speed and error, normally low, becomes even lower in the psychotic group.

It is possible to speculate, then, that there is a disability which can be produced in psychotics which is independent of the disability which produces their slowness of thinking, and that this second disability leads them to make more errors in problem-solving. It is conceivably some abnormality in the checking mechanism. What specific symptom this might be related to it is not possible to say. It was pointed out earlier that abnormal cognitive slowness was probably not common enough or severe enough among psychotics to account entirely for their low general level. An abnormal error tendency would

help to explain the serious impairment of general level among the more deteriorated psychotics.

Summary and Conclusions

1. There are possibly two causes of "error" on cognitive tests in abnormal people.

2. Extraverts are more careless and impulsive, and tend to make more errors, probably for these reasons. This can in part explain why they perform tests of general level more poorly.

3. Psychotics may suffer from some disability, possibly unrelated to the cause of their intellectual slowness, which causes them to make more errors than normals. It is possible that this can account for some of their general intellectual deterioration, especially in chronic cases.

(d) Distractibility

It would seem reasonable to expect mental patients to be handicapped on cognitive tests by their other symptoms. People who are deeply depressed, who hear voices, or who are fearful of what others may do to them could not really be expected to concentrate on tests as well as normal people. One need not postulate abnormal distractibility, but merely an abnormal number of distractions. However, one carefully elaborated theory about the nature of schizophrenia rather surprisingly predicts that schizophrenics are peculiarly immune to distraction.

Bleuler believed that in schizophrenia mental processes become increasingly fragmented and unconnected. Kretschmer (1928, 1951) elaborated this theory considerably, and inspired a considerable amount of objective research. In essence Kretschmer holds that there is a fundamental "constitutional" variable schizothymia-cyclothymia which has numerous correlates both physical and mental. Schizothymes tend to be leptosomatic in body build, and also tend to develop schizophrenia. Cyclothymes tend to be pyknic in body build and tend to develop manic-depressive psychosis. Psychotic individuals in fact merely represent extremes on this constitutional continuum. The main psychological trait associated with schizothymia-cyclothymia is that of "dissociation" (*Spaltungsfähigkeit*). Dissociation is the ability to perform several mental activities (or to maintain several mental "sets") simultaneously with very little mutual interference or modification. Kretschmer interpreted a number of findings as supporting the theory that schizothymes and schizophrenics are extremely dissociated. For example, Van der Horst (1924) and Kibler (1925) found schizophrenics to be less distractible in a reaction-time situation, Kibler (1925) found schizophrenics better able to ignore "irrelevant" stimuli in a tachistoscopic perceptual test, Enke (1928) and Enke and Heising (1929) found

leptosomes better at simultaneous mental additions, and Enke (1929, 1930) found leptosomes better able to do two physical tasks simultaneously. However, these findings did not arise out of carefully controlled studies, and indeed many of the early studies were probably contaminated in that the diagnosis was not made independently of the test results. Brengelmann (1954) in an extensive review of this literature concluded that there is no real evidence for any of these statements, since more carefully controlled studies (Mohr and Gundlach, 1927; Enke, 1928; Dambach, 1929; Reiter and Sterzinger, 1931; Klineberg *et al.*, 1934; Braat, 1936; Mountford, 1939; Kerck, 1940, 1944; and Eysenck, 1952) completely fail to support these results. Payne (1955) demonstrated that there is no evidence for the existence of a trait of dissociation in normal people, as a large number of Kretschmer's tests failed to reproduce more than an insignificant matrix of intercorrelations. In fact this study suggests that in normals, at least, the ability to perform two tasks simultaneously is very specific, and depends entirely on the nature of the tasks. Thus Kretschmer's theory must be discarded.

Norman Cameron (1951) has produced a hypothesis much more in line with common observations than Kretschmer's theory. He suggested that one factor which disturbs problem-solving in schizophrenic patients is the "interpenetration of personal themes." Their line of reasoning is distracted by some personal thought which intrudes itself and may even become mixed up with the problem itself. This disturbance also manifests itself in the form of "scattered speech," a disorganization of the logical sequence of speech, with long pauses and the use of inappropriate words. Cameron and Magaret (1949) were unable to produce scattered speech in normals who were doing a sentence completion test under ordinary conditions of distraction (listening to case reports played phonographically). However a "personal" distraction was effective. Hassol, Magaret and Cameron (1952) distracted normal subjects by playing them (through earphones) the recorded sound of their own voice giving a T.A.T. story while they were attempting to make up a story to a second T.A.T. card. Under these conditions their speech became disorganized, illogical, and full of pauses, and words were used inappropriately. Cameron and Magaret (1950) found that in normals, those who are "cheerful," "calm" and "non-introspective" are more prone to develop scattered speech with distraction than others. This suggests that extraverts may be more distractible than introverts.

Davis and Harrington (1957) report a rather different investigation. Fifty normal and fifty schizophrenic subjects were presented with sets of thirty-two pictures. They were given five pieces of information which would allow them to select only *one* picture in

each set. Some sets contained human figures, while some were non-human. When a group of normals and a group of schizophrenics were matched for their ability to do the non-human problems it was found that the schizophrenic group was significantly worse at doing the human problems. On the other hand, two groups matched for ability on human problems did not differ on non-human problems. The study suggests that schizophrenics might well be distracted by human stimuli which produce disturbing personal thoughts which interfere with test performance.

Whiteman (1954) reported a similar investigation. Thirty-one schizophrenics and thirty-one carefully matched normal controls were given a Verbal analogies test, a Picture reasoning test and a Social Concept test. The Social Concept test consisted of a series of cards picturing human figures which together illustrated a concept such as "rescue." The schizophrenics were worse at all three tests than the normals, but they were worst at doing the Social Concept test, presumably due to the "interpenetration of personal themes" produced by the more distracting human content. The Social Concept test differentiated significantly when the differences between the two groups on the other measures had been partialled out.

Thought "blocking" has long been regarded as an important abnormality of schizophrenic thought. It is difficult, however, to demonstrate objectively on cognitive tests. Eysenck reports a rather interesting method of demonstrating it (Eysenck *et al.*, 1957). Twenty neurotics, one hundred and six normals and twenty psychotics were given the Nufferno speed test. The log time scores of normals are normally distributed on this test. "It was hypothesized that the familiar 'blocking' phenomenon in the thinking of psychotics might lead in this group to an excess of very long reactions, thus effectively causing a skew in the distribution of log time scores. This was done by calculating rough indices of skew . . ." "Skew" scores differentiated the groups at the 0.1 per cent level, the psychotics having much more skewed time distributions than the neurotics or the normals. It has never been proved that blocking is the result of some internal distraction, although this is a reasonable hypothesis.

It seems likely that the importance of the effect of distraction on the cognitive test performance of abnormal subjects has been underestimated. Cohen (1952*b*), separately factor-analysing the Wechsler-Bellevue subtest scores of one hundred neurotics, one hundred schizophrenics and one hundred brain-damaged patients concluded that the third important factor isolated could be labelled "freedom from distractibility." Wittenborn and Holzberg's (1951*a*) investigation relating the Wechsler-Bellevue subtests

to the Wittenborn symptom rating scale has already been described. When nine "syndrome" scores were intercorrelated with the Bellevue subtest for seventy-nine mental patients, very few correlations were significant. The general intellectual superiority of the hysteric patients (as rated) compared with psychotics can account for six of the significant correlations obtained. The only other large group of correlations was that with the symptom cluster "excitement." The correlations were: — 0.252 with Digit Span, — 0.263 with Similarities, — 0.245 with Picture arrangement, — 0.268 with Block Design and — 0.281 with Digit Symbol. In each case "excited" patients did poorly. The symptom cluster Excitement refers to such symptoms as "spontaneous change in ideas, constant movement, compulsive acts, variations in rate of speech . . . unawareness of others, loudness, incontinence, delusional thinking and hallucinations" (Wittenborn, 1951). It seems likely that such patients would be extremely distracted while performing intelligence tests.

Wittman (1937) gave one hundred schizophrenics, thirty G.P.I. cases and thirty normals a number of cognitive tests. In the schizophrenic group, the correlations between test scores and a rating of co-operativeness ranged from 0.58 to 0.94. Rappaport and Webb (1950) report a correlation of 0.64 between the Elgin Test Reaction Scale and I.Q. for a group of ten schizophrenics. Rappaport (1951) reports a correlation of 0.89 between behavioural accessibility as measured by the Elgin Test Reaction Scale, and a vocabulary test score in two hundred and fifty-six schizophrenics. In a third study (Rappaport, 1953) on forty-two organics and eighty-five schizophrenics using seven cognitive tests, including the Wechsler-Bellevue, uncooperative subjects as rated by the Elgin scale were significantly worse than co-operative subjects on all the tests used. All these results are consistent with the hypothesis that the test scores of many psychotics are reduced partly because they are distracted by their symptoms.

Foulds (1951) reports an interesting attempt to bring distractibility under experimental control. Using a modified form of the Porteus Maze test, he found that a group of dysthymic neurotics was much slower than a group of extraverted neurotics both on "starting time" and "tracing time." Foulds hypothesized that the introverted subjects were especially distracted by their worries and anxieties. He argued that if some form of experimental distraction were given, the extraverted group should do much worse, while the introverted group should remain much the same. The distraction used was simply counting aloud while performing the mazes. As predicted the groups differed significantly in the effect of the distraction. In fact the dysthymic group actually became

faster on both measures. Presumably the second distraction (counting) prevented the occurrence of the first distraction (their thoughts) and was actually less handicapping. Foulds (1952) also demonstrated the same phenomenon in a group of depressed patients.

Kessell (1955) and Campbell (1957) were unable to repeat these results on groups of mainly psychotic patients (schizophrenics and depressives) and brain-damaged cases. They found that all the groups improved on retest with the distraction, and that this improvement could be attributed to practice. This lack of agreement may partly be due to the rather different patient groups used. Thus, while there is some doubt whether the effect of distraction can be controlled in the way suggested by Foulds, these studies do not disprove the contention that distraction is an important factor in the production of low test scores in many abnormal groups.

Summary and Conclusions

1. The effect of distraction on reducing scores on cognitive tests in mental patients has probably been underestimated. Very high correlations between ratings of co-operativeness and general distractibility, and the scores on a wide range of tests have been reported in psychotic groups.

2. Distraction probably affects timed tests much more than untimed tests.

3. A great deal of the deterioration found in cases of affective disorder on cognitive tests (which is as great or greater than that found in schizophrenia) may be due to distraction. Individuals whose main symptom is profound depression, with feelings of guilt and unworthiness from which they cannot free their minds, may obtain low test scores largely because they are unable to attend and concentrate.

4. Distraction may be the main cause of abnormal cognitive slowness in many depressed patients.

5. While few specific data are available, it is likely that manic patients are slow, and obtain poor g scores because they are abnormally excitable and distractible.

6. While dysthymic neurotic patients may be more distracted by their symptoms (anxieties, guilt feelings), extraverts may be more easily distractible than introverts.

(e) Memory Span

"Span of apprehension" or "immediate memory span" is in many ways a curious and complex phenomenon. Perhaps the most satisfactory account of it has been given by Broadbent (1957). If this theory is accepted, there is every reason to believe that immediate memory span is quite unrelated to learning and long term retention (*see also* Inglis, 1957). Broadbent

believes that incoming information is held in temporary store until some action can be performed on it, by some form of mechanism which "circulates" it, feeding it back into the perceptual system at the end of each circuit. This circulating mechanism, however, can only hold (and circulate) a limited amount of information (a "bit" of information is not to be identified with a "stimulus"). If information is held *without* circulating, it disappears after a short time has elapsed. Broadbent's "information theory" model, while simple, accounts for many known facts. If it is accepted, individual differences lie in the capacity of this circulating mechanism.

Unfortunately, tests of memory span have one grave drawback for use with abnormal subjects. It is never possible to discover whether the subject's memory span is small, or whether he merely failed to perceive the material in the first place simply because he was distracted. In fact Wittenborn and Holzberg (1951*a*), as has been mentioned, found the Digit Span subtest of the Wechsler-Bellevue to have a correlation of -0.263 with the symptom cluster "excitement," a result already attributed to the distractibility of this group of patients. All the data discussed in this section are therefore ambiguous.

The reasons for believing immediate memory span to be an important determinant of score on many cognitive tests have been discussed in the first section. A poor memory span as such could clearly be a factor contributing to a reduction of general level in abnormal subjects.

The Digit Span subtest of the Wechsler-Bellevue scale is one of the most resistant to age in normal people (Doppelt and Wallace, 1955). However, it is influenced by other factors. Maher (1952) investigated the effect of set on digit span. Some series were given in a generally ascending order, some in a generally descending order, and some randomly. This introduced an expectancy which significantly determined the direction of errors. However normals and mental patients were not differentiated in terms of the type of error made.

Klugman (1948), testing three hundred neurotics, found a significantly reduced digit span when the test occurred at the *end* of the Wechsler-Bellevue, suggesting that fatigue conceivably reduces span of apprehension.

Moldawsky and Moldawsky (1952) found that normals have a decreased digit span when tested under anxiety-producing conditions, and Kaye *et al.* (1953) found that normals who complain of a high degree of test anxiety (on a questionnaire) have a lower immediate memory span than those who complain of very little test anxiety (when given group tests of memory span).

Anxiety in normals thus appears to reduce memory

span, and there is some evidence that neurotic patients have a slightly below average memory span. Brengelmann (1958*a*) found no differences in memory span (using a five-second exposure of a pattern of figures) between two neurotic and two normal groups. However, the data from the Wechsler-Bellevue subtests presented in Table VI.12 show that Digit Span is the lowest subtest in the introverted neurotic and extraverted neurotic groups.

There is considerable evidence for a reduced memory span in psychosis. Van der Horst (1924) found psychotics to be poorer than normals. Eysenck (1952) and Sybil Eysenck (1955) found psychotics to be inferior to both normals and neurotics. Brengelmann (1958*b*) found psychotics to be inferior to neurotics only when a thirty-second exposure time was used, but not when a two-second exposure time was used. Cohen (1950) found psychotics to be inferior to neurotics on the Wechsler Memory Scale, a test containing many items of immediate memory span.

Although Kibler (1925) found manic-depressives to have a better memory span than schizophrenics, these results were not repeated by Braat (1936), Mountford (1939) or Eysenck (1952).

Cameron (1940) found that eighteen senile psychotic patients had an abnormally poor immediate memory span.

There are no studies relating memory span to introversion-extraversion as such. We have already seen that on the Nufferno (letter series) tests, extraverts are quicker, but make more errors than introverts. It is conceivable that this could be a function of memory span. Individuals (introverts) with a large memory span, might be able to hold the entire series in mind at once, and seek a solution which fits the entire series by examining all the possible permutations and combinations of the letters. Individuals with a small span (extraverts) might break the series in half, producing a solution based on two shorter, and in some cases indeterminate series. While this would be much quicker (there being fewer permutations and combinations to examine) it would be less accurate.

Summary and Conclusions

1. There is some evidence that memory span is reduced by anxiety in normal people.

2. Neurotics tend to have a lower memory span than normals.

3. Psychotics are lower than both neurotics and normals, although there are no differences between schizophrenics and manic-depressive psychotics.

4. These data are ambiguous, since they could be due to distraction or to true differences in the capacity of the mechanism of immediate memory. The differences are, however, strikingly similar to the differences between the groups produced by distraction.

(f) Learning

Although this subject is treated in detail by Jones, it is not possible to separate learning and cognition completely. Some cognitive tests such as vocabulary and information tests are merely measures of long-term retention, and are partly a function of the individual's past learning ability. Many other tests (e.g. some performance tests) are partly dependent on *present* learning ability, since new methods of manipulating material must be acquired during the course of the test. It has already been pointed out that in the older age groups, as learning ability declines, it probably becomes an increasingly important determinant of many test scores.

Inglis (1958), reviewing the literature on cognitive dysfunctions in elderly psychiatric patients, concludes that there is considerable evidence that some groups obtain lower scores on the Wechsler Performance Scale than the Wechsler Verbal Scale. He attributes this to their inability to learn new material. They do, however, tend to retain what they have learned in the past. Botwinik and Birren (1951) also conclude that senile psychosis is associated with defective rote-learning ability.

Inglis (1957) demonstrated that severe "memory impairment" in old people is probably due, not to an inability to retain information, but to a learning disability. In other words, these patients never register facts in the first place, so that they have nothing to forget. On the other hand, they tend to remember what they have learned in the past before they developed their learning defect.

Age is not the only factor which is related to learning however. Extraverts are poorer at learning than introverts. This fact can account to a large extent for the differences in general level discussed in the first section. Introverted neurotics, who have a higher learning ability also have high I.Q.s (see Table VI.2). Extraverted neurotics whose learning ability is worse, obtain lower I.Q.s. If we can regard delinquents or psychopaths as even more extraverted, it is not surprising to find that they have the lowest I.Q. of the three groups. These individuals tend to do poorly at school, and get low scores on tests involving the acquisition of information (e.g. Wechsler Verbal as opposed to Performance items—see Table VI.11).

Rote-learning ability as such is less clearly related to the test performance of psychotics. By and large, psychotics seem to derive as much benefit from practice when they are retested on intelligence tests as do normals (Rabin, 1944b; Hamister, 1949; Derner *et al.*, 1950). Learning in psychotics will be discussed again later.

Summary and Conclusions

1. Old people, and especially cases of senile psychosis are poor at rote learning and thus do worse on tests

involving "present learning ability" (e.g. performance tests) than tests involving the retention of information learned in the past (e.g. information, vocabulary).

2. Memory disorders in the aged are probably learning disorders in the sense that facts are not remembered because they are not learned.

3. The relationship between learning and introversion-extraversion can partly account for the differences in general cognitive level between different neurotic groups. Dysthymics are best at learning, and have the highest I.Q. Hysterics are worse at both learning and intelligence test performance, and psychopaths are lower still.

(g) Retention

Hull pointed out as early as 1917 that in order to measure individual differences in long-term retention, it is essential to ensure that all subjects have learned the information to the same criterion. If this is not the case, retention scores will be a function of both the ability to learn, and the ability to retain, and will thus be quite ambiguous. Unfortunately there appear to be no studies of abnormal subjects in which retention has been adequately measured. Routine memory tests such as the Wechsler Memory Scale combine measures of rote learning, span of apprehension and long-term retention (inadequately controlled) as if they were identical functions, and thus produce completely inconclusive results.

There is some evidence in normal people that, just as some material may be harder to learn because it is "traumatic" and presumably produces conditioned avoidance responses (Cowen *et al.*, 1955; Jacobs, 1955), some material may be harder to recall once learned for the same reason (Garber, 1955; Klugman, 1956). There is also evidence that normal people may distort what they recall in ways which are related to specific personality characteristics (Davids, 1955). All these phenomena might be expected to occur in abnormal subjects, but no specific studies have been done.

The only generalization which appears warranted, is that those cognitive tests which appear to be least affected by any ability other than the capacity to recall information learned in the past (e.g. Vocabulary tests, the Wechsler Information subtest) seem least affected by mental illness. It is reasonable to conclude that apart from some organic conditions (e.g. aphasia), retention is not greatly affected by either psychosis or neurosis. Low scores on these tests could of course be obtained through uncooperativeness or extreme distractibility. It is curious that a large proportion of most routine psychiatric examinations of mental status is concerned with assessing long-term retention by means of personal information and general knowledge tests.

Summary and Conclusions

1. There are no adequate studies of long-term retention in abnormal subjects in which learning ability has been controlled.

2. What evidence there is suggests that retention may be almost completely unaffected in functional psychiatric disorders, although some patients may obtain low scores on information tests for other reasons (e.g. the inability to attend).

(h) Drive

In a previous section it was concluded that there is probably a curvilinear relationship between cognitive speed and neuroticism, individuals who are moderately neurotic being faster than very stable or very neurotic individuals. It is tempting to hypothesize that this is due to drive, there being some evidence for a curvilinear relationship between drive and learning (see Chapter 13). The "drive" concerned would probably be anxiety, since it is reasonable to regard neurotics as being more anxious than stable people.

There is a fairly large body of literature relating anxiety to cognitive test performance in normal people. Unfortunately the findings are somewhat contradictory, so that, although tentative generalizations can be suggested, no firm conclusions can be drawn.

Kerrick (1955) and Calvin *et al.* (1955) reported a consistent tendency on a wide variety of cognitive tests for anxiety as measured by the Taylor Anxiety Scale to be negatively correlated with test score. Anxious subjects were consistently poorer. Zweibelson (1956) reported that in children, situational anxiety produces a decrement in test performance.

On the other hand, Schulz and Calvin (1955) and Mayzner *et al.* (1955) found *no* significant correlation between the Taylor Anxiety Scale and I.Q. in normals, and Siegman (1956a) and Matarazzo (1955) found insignificant correlations in psychiatric patients. Shoben (1950) similarly found that anxiety as rated by the Cornell index appeared to have none of the usually expected effects on the Wechsler-Bellevue test.

These contradictory findings might, of course, be expected if the relationship between I.Q. and anxiety is curvilinear. Both very high and very low anxiety could produce a reduced score, and these studies could have selected groups at different anxiety levels. Such a relationship was in fact reported by Sarason and Mandler (1952) on two hundred and ninety-two students. While test performance was curvilinearly related to anxiety, moderately anxious students doing best, there was no relationship between anxiety and academic work over the year, where presumably stress factors were minimal. Sarason, Mandler and Craighill (1952) obtained a similar curvilinear relationship between the performance on a digit symbol test and

level of anxiety, in an experiment in which degree of stress was experimentally manipulated. Matarazzo and Phillips (1955) found a curvilinear relationship between the Taylor Anxiety Scale and digit symbol performance, but it was not statistically significant. Goodstein and Farber (1957), in a nearly identical study, also failed to obtain a significant curvilinear relationship.

One explanation for these positive and negative results might be that some element of *stress* is needed. It is not sufficient merely to correlate an anxiety scale with performance and expect to find a curvilinear relationship. This will only occur if, *during the test*, sufficient stress is applied (at least to normals) so that the people who report themselves anxious on a questionnaire are actually *made* anxious during the experiment. This was the case in the study by Sarason, Mandler and Craighill (1952), and some degree of stress probably operated in the study of Sarason and Mandler (1952). In both these experiments a significant curvilinear relationship was obtained.

One possible method of ensuring that potentially anxious subjects are made anxious during the test is to frustrate them. This was done in an experiment by Waterhouse and Child (1952). Normal subjects were given various cognitive tests under conditions of interference and non-interference. Subjects who claimed that interference upset them (on a questionnaire given previously) did worse (high anxiety group). Subjects who claimed that interference did *not* upset them actually did better in the stressful conditions (low anxiety group). The complexity of the cognitive tasks involved seemed to make very little difference in this experiment. A very similar study with very similar results was reported by Mohsin (1954), using as a cognitive measure the speed of performing the Passalong test.

McKinney *et al.* (1951) reported an experiment in which one hundred and ninety-six naval trainees were required to count different sorts of symbols as quickly as possible in normal conditions, and then with interruptions. The stress made them less accurate, but *faster* (in that more problems were attempted). The group's performance was relatively homogeneous, and uncorrelated with their response to a questionnaire, but, if it is assumed that this was a very stable group with low anxiety, these results are consistent with the hypothesis that it is *speed* which is curvilinearly related to drive level. That is, in the experiments discussed so far, the moderately anxious groups do better on tests than the extremely anxious or extremely stable groups merely because they work *faster*. This was clearly the case in Mohsin's (1954) experiment, and Mandler and Craighill's (1952) results were derived from a digit symbol test, where speed is

extremely important. It is of interest that Castaneda (1956) found that reaction-time speed increases with increased stimulus intensity much more in an anxious than in a non-anxious group of normals.

Mandler and Sarason (1952a) found that a high anxiety group increased their speed of performing a Koh's Block test with practice much more than a low anxiety group. When stress was added, however (an intervening progress report—its nature did not matter), the high anxiety group became slower and the low anxiety group, faster. In a second study, however, the results before stress were not repeated although added stress still decreased the speed of the high anxiety group (Mandler and Sarason, 1952b).

Siegmán (1956b), testing thirty-six medical and psychiatric patients, found that a high anxiety group (Taylor Scale) obtained poorer scores on the Matrices when it was given timed (stressed?), while a low anxiety group did better on the timed version of the test.

Furieux has obtained very similar results with the Nufferno speed tests in normal students. The speed tests can be given in two ways. In the unstressed tests, subjects work at their own speed, and do not know that they are being timed. In the stressed tests, subjects are told to work as quickly as possible, and are aware they are being timed. The added stress *decreases* the speed of a very neurotic (high drive) group, but increases the speed of normal people (low drive group). Neuroticism in this case is assessed by the Guilford-Martin S.T.D.C.R. inventory.

It is possible then, to draw the following tentative conclusions from these studies. Individuals who are performing in a state of low drive *at the time of testing* tend to be slow at cognitive tests. Individuals who are in a state of medium drive tend to be fast. However, individuals in a state of very high drive tend again to be slow. Such evidence as exists, however, only relates to anxiety as a drive.

Maltzman (1955) argues from Hull's theory that high drive can in fact alter the *difficulty level* of cognitive problems. In hard problems, the correct response (an "internal" $S^H R$) has a lower habit strength than the incorrect responses. However, as drive level increases, the effective reaction potential ($S^E R$) of the wrong responses will become even greater than that of the correct response since $S^E R$ is a product of D and $S^H R$.¹ If this is the case, people

¹ Maltzman gives a rather unconvincing "quantitative" example of this, as follows—

For low drive, suppose for the *correct* response,

$$S^H R = 2, D = 1, S^E R = 2.$$

For the *incorrect* responses, $S^H R = 5, D = 1, S^E R = 5$.
Thus $S^E R$ *incorrect* minus $S^E R$ *correct* = 3.

However for high drive, for the *correct* response (if drive is doubled), $S^H R = 2, D = 2, S^E R = 4$.

For the *incorrect* responses, $S^H R = 5, D = 2, S^E R = 10$.

Thus $S^E R$ *incorrect* minus $S^E R$ *correct* = 6.

with high drive should find difficult tests much harder to do than easy tests, in comparison with people of low drive. While there is some evidence that this is the case for measures of learning (see Chapter 13), the only study investigating this relationship in cognitive tests (Waterhouse and Child, 1952) found no evidence that difficulty level and drive interact in this way. Child and Waterhouse (1953) prefer a different explanation, which perhaps fits the present data better. They argue that very high anxiety becomes distracting, as it produces conditioned responses of its own which interfere with the task.

This explanation is even more satisfying because it allows us to explain a fact discussed earlier. Extraverts (at the same average level of neuroticism) are considerably faster than introverts on cognitive tests. If we accept that introverts condition more easily than extraverts, it follows that they will have acquired more distracting conditioned responses to their anxiety than extraverts. These responses might be of two sorts. Some people might only have distracting thoughts (fears, etc.) which have become conditioned to a high anxiety level (anxious responses). Other people might have learned some ritual which serves the purpose of reducing their anxiety. This would probably be an obsessional tendency to check and recheck their answers (repeating the problem-solving search process). This would, of course, make their work more accurate, and we have already seen that introverts are more accurate than extraverts.

Indeed all the facts so far discussed about slowness in normals and neurotics could be included in the sort of framework discussed in detail in Chapter 13. The curvilinear relationship found between neuroticism (or anxiety as a drive) and speed might be an artefact produced by combining the data for extraverts and introverts. This would help to explain some of the earlier conflicting results, which

It might appear that in the high drive state, the wrong responses are twice as probable.

However, Maltzman nowhere defines the *units*. In the context of this argument the basic unit is clearly "probability of evocation of response." If we re-state the example in terms of *probabilities*, we get the following—

In the *low drive* state, for the *correct* response, $D = 1, S^H R = 0.2, S^E R = 0.2$ = probability of *correct* response occurring. For the *incorrect* responses, $D = 1, S^H R = 0.8, S^E R = 0.8$ = probability of *incorrect* responses occurring.

In the *high drive* state, for the *correct* response, $D = 2, S^H R = 0.2, S^E R = 0.4$ = probability of *correct* response occurring. For the *incorrect* responses, $D = 2, S^H R = 0.8, S^E R = 1.6$ = probability of *incorrect* response occurring. The second set of probabilities is obviously nonsense. In fact probabilities cannot be multiplied in this way. Note, however, that the *ratio* of *correct* $S^E R$: *incorrect* $S^E R$ remains the same at both levels of drive. The *proportion* of *right* to *wrong* responses thus remains the same at both drive levels. This example perhaps illustrates the dangers of quantification in psychology when the units are not specified. It must be noted that Spence (1956) is able to advance this sort of argument in such a way that the probabilities concerned do not add up to more than unity.

could be due either to a failure to produce real differences in drive or a product of the extent to which the subjects were introverted or extraverted.

It is conceivable that *unconditioned* anxiety is linearly related to speed. This could be because anxiety, like an overactive thyroid, in some way speeds up the mechanism of the search process at an unspecified physiological level. Were it not for *conditioned* anxiety responses, extremely neurotic subjects would be fastest of all. This leads to the prediction that the fastest group will be extremely extraverted neurotics. It is also possible that the number of conditioned anxiety responses produced is linearly related to the amount of anxiety present, and linearly related to the degree of *introversion* (conditionability) of the individual. Furthermore it is possible that a large number of conditioned anxiety responses produces a distraction (or an obsessional tendency) which outweighs the advantage of high drive. If all this were true, the slowest group of all would be the extremely introverted neurotic group who, as soon as a modest state of anxiety (drive) developed, would also develop a large number of distracting responses. The second slowest group would be the stable introverts, who would have less drive, and therefore would develop slightly fewer distracting responses than their neurotic counterparts. The second fastest group would be the very extraverted stable group, who would develop a little less drive than their neurotic counterparts, but who would also be free of any distracting conditioned anxiety responses.¹

Curiously enough, Furneaux's analysis of speed-test results in normal students bears out all these predictions. If one measures the extent to which subjects speed up when asked to work as quickly as possible (on the stressed speed test), the highest "stress gain" scores are obtained by neurotic extraverts.² The second highest scores are achieved by stable extraverts. Lower still are stable introverts, and lowest of all, neurotic introverts, many of whom become much slower when stressed in this way.

This account must, of course, be regarded only as an hypothesis. A somewhat different hypothesis was discussed in the section on memory span in which it was stated as possible that introverts might solve letter series items in longer units, thus becoming

slower but more accurate. These two explanations are not entirely incompatible, as this is clearly a more thorough (obsessional) method of working which could serve to reduce the level of anxiety. The two hypotheses could, of course, be complimentary, both factors accounting for part of the observed differences.

Summary and Conclusions

1. The data relating drive to cognitive performance are somewhat conflicting, and only tentative hypotheses can be suggested.

2. There may be a linear relationship between *unconditioned* anxiety and speed of problem-solving, high anxiety producing high drive and fast performance. This could partly explain why neurotic subjects as a group are of above average general intelligence.

3. A high degree of introversion (conditionability) could produce a large number of distracting conditioned anxiety responses (or obsessional checking tendencies) themselves correlated with level of anxiety, which could slow down cognitive test performance more than high drive, by itself, speeds it up. These obsessional rechecking tendencies could, however, be responsible for the reduction in error found in introverted groups.

4. These two relationships when added together, could produce in a heterogeneous group a tendency for cognitive speed to appear to be related curvilinearly with neuroticism, or level of anxiety.

5. Because of these relationships, extraverted neurotics, when tested in a state of high drive (produced by "stress"), will work fastest, stable extraverts less fast, stable introverts slower, and introverted neurotics slowest of all.

(i) Rigidity

Rigidity has for many years been regarded by some writers as a personality variable of considerable importance. It was thought to account for a wide range of behaviour. As early as 1915, Lankes developed a questionnaire listing various rigid personality traits, which he administered to forty-seven normal subjects. He also gave them a wide range of tests, all of which he thought would be influenced in some way by rigidity (Lankes, like many earlier writers, uses the term *perseveration*). The tests included a cancellation test requiring a shift in the middle to another letter, a test of tapping speed (fast tappers he thought should *perseverate*), a colour wheel experiment to determine at what speed red and green blend to form grey (*perseverators* should see a blend at slower speeds), memory tests, a test of distractibility, word association tests, and even essays to write (*perseverators* should be good at long essays but poor at short ones). Lankes

¹ Another prediction follows from this explanation. In experiments in which introverts and extraverts are combined, and in which a "spurious" curvilinear relationship between anxiety drive and speed is found, the speed variance should increase enormously with increased anxiety. That is, the low drive group will be fairly homogeneous, but the high drive group, due to their heterogeneous reactions to high drive, should show very much variance about their mean.

² In each case these descriptions are based on responses to "extraversion" and "neuroticism" questionnaires (derived from the Guilford-Martin S.T.D.C.R. scales), the subjects being divided up into the four quadrants as they fall above and below the means of the two measures.

reported that *all* these measures correlated in the predicted direction with his rigidity questionnaire.

Lewin (1935, 1936) and Kounin (1941, 1948) believe that rigidity might be related to some fundamental property of the brain, which prevents one behavioural "region" from interacting with and modifying an adjoining region. This theory is very reminiscent of Kretschmer's theory of "dissociation" already discussed, and Goldstein's general theory of "isolation" (Goldstein, 1939, 1942). Kounin (1941, 1948) believes that rigidity increases with age, and performed several experiments using different measures of rigidity to demonstrate this.

Unfortunately, just as there is evidence (Payne, 1955) that different tests of dissociation have nothing in common, there is very strong evidence that there is no general factor of rigidity. In fact, no one has ever succeeded in repeating Lanke's (1915) results in detail. Studies by Jasper (1931), Shevach (1937), Notcutt (1943), Kleemeier and Dudek (1950), Goodstein (1953), Rim (1953), Forster *et al.* (1955), Davids (1955b) and Wolpert (1955) all report a complete failure to obtain a general factor of rigidity. Indeed, in many cases, none of the tests intercorrelated significantly. Even when rigidity tests are given under conditions of stress, a general factor fails to emerge. In fact stress does not alter the intercorrelations significantly (Appelzweig, 1954; French, 1955).

There is some evidence that certain motor tests of rigidity produce two relatively specific factors (Cattell, 1946; Cattell and Tiner, 1949; Schaie, 1955) and some of these tests have been found to correlate with personality variables (Pinard, 1932; Eysenck, 1947, 1952).

The best factorial study of mental rigidity tests is reported by Guilford *et al.* (1957), who found evidence for two independent and relatively specific mental rigidity factors. One was labelled Adaptive flexibility, and was: "the ability to change a *set* in order to meet the requirements imposed by changing problems." The other was labelled Spontaneous flexibility, and was: "the ability to produce a diversity of ideas in a relatively unstructured situation."

The factor of adaptive flexibility is very similar to *Einstellung* rigidity, which Dunker (1945) described in his analysis of problem-solving. Dunker's analysis, while convincing, is mainly on a logical level and no experiments appear to have been performed to determine how important *Einstellung* rigidity might be in the solution of different types of standard cognitive tests.

By far the most frequently used measure of *Einstellung* rigidity is Luchins's "water-jar" test (Luchins, 1942, 1951; Luchins and Luchins, 1950). While Guilford did not use it in his factor analysis, it is very similar to tests of adaptive flexibility. In Luchins's

test (which has several variations), subjects are given a series of problems which require them to state how a given quantity of water might be measured out if they had three containers of known capacity. During a series of "set" problems, the subject finds that a certain complicated series of manoeuvres always produces an answer. These are followed by problems which can be solved very simply (by using two of the three containers), or by the complicated method which has been learned. Rigid people will continue to employ the complex method, while flexible people will change to the simple method. A very similar letter-maze test of *Einstellung* rigidity has been developed by Cowen *et al.* (1953), and shown to correlate significantly with the water-jar test.

There have been numerous attempts to relate *Einstellung* rigidity to other aspects of behaviour. Many investigators have tried to demonstrate that it is correlated with rigid behaviour in general as assessed by a questionnaire, but by and large the results are conflicting and inconclusive (Schmidt *et al.*, 1954; Rokeach *et al.*, 1955; Wolpert, 1954; Goodstein, 1953; Pitcher and Stacey, 1954; Cowen and Thompson, 1951). Similarly, attempts have been made to demonstrate that prejudiced people are especially rigid, by seeking correlations between *Einstellung* rigidity and the California Ethnocentrism scale. Again the results have been conflicting and inconclusive (Rokeach, 1948; Levitt and Zelen, 1953; Jackson *et al.*, 1957; Brown, 1953).

One line of research, however, has produced relatively consistent results. There is evidence that when normal subjects are tested under *stress* they become more rigid, both on some perceptual tests of rigidity (Smock, 1955a, 1955b; Erikson and Wechsler, 1955; Moffitt and Stagner, 1956) and on the Luchins test of *Einstellung* rigidity (Cowen, 1952a, 1952b; Maher, 1957).

This finding is perhaps not surprising. The development of *Einstellung* rigidity in Luchins's test is clearly a learned phenomenon, very similar to ordinary discrimination learning (i.e. some types of solution, and perhaps perceptions, are rewarded and some are not during the development of the set). It would seem probable that individuals who are better at learning would develop this set more easily. Since an increase of drive produces quicker learning, it is reasonable that an increase of anxiety produced by stress should make people more rigid on the Luchins test.¹ One might predict that for this reason introverted people would tend to be more rigid under stress than extraverted people. Indeed, psychiatrists often maintain

¹ Malmö and Wallerstein (1955) predicted that the "rigid" solution might ultimately extinguish through the development of "reactive inhibition" were it repeated often enough. However they did not test this prediction.

that introverted neurotics are more rigid in this sense. Unfortunately no studies investigating differences between neurotic groups or even between neurotic and normal groups appear to have been done with this test. It is interesting that Rokeach (1950) reports that, given longer over the test, normal people are less rigid, while Levitt and Zelen (1953) find the reverse, that speeded conditions produced flexibility. (Levine, 1955, found no relationship between *Einstellung* rigidity and speed of decision.)

There is much less work on the second sort of mental rigidity, Spontaneous flexibility. There is no evidence that it is related to stress in the same way. Ross *et al.* (1952), using the Wisconsin sorting test to determine how easy it was for normals to "shift" to a different method of sorting, found that the stress of being shocked had no effect on performance, and Wesley (1953) found the same measures of rigidity to be unrelated to the Taylor Anxiety Scale. McAndrew (1948) demonstrated that experience may be related to this sort of rigidity, as deaf children are much less able to shift (think of new methods of sorting) on a sorting test than normal children. Blind children, however, were normal in this respect.

Much has been written about rigidity in schizophrenia by Goldstein and his followers. Goldstein, while drawing a theoretical distinction between rigidity and concreteness (Goldstein, 1942), believes they both result from "isolation" in the nervous system (Goldstein, 1939), and in practice uses the same "concept formation" measures for both rigidity and concreteness (Goldstein and Scheerer, 1941). The discussion of the results from these tests will be left until the next section. It is interesting that Luchins (1951*b*), rating concreteness from the responses to a Similarities test, found no correlation with *Einstellung* rigidity as measured by the water-jar test.

While there are studies investigating motor rigidity and perceptual rigidity in psychotics (Stephenson, 1932*a*, 1932*b*; Pullen and Stagner, 1953), there are no satisfactory studies of adaptive flexibility in psychosis. Miller (1951) found that schizophrenics were more rigid in setting their level of aspiration in an experiment, than other groups. Jost (1955) found this true only of paranoid schizophrenics. There is no reason to believe that this sort of rigidity is related to either type of intellectual rigidity, however. Since the studies of rigidity in psychosis are inextricably bound up with studies of concept formation, this subject will be discussed further in the last section.

Summary and Conclusions

1. There is no general factor of rigidity, so that it is not possible to generalize about rigidity tests.
2. Guilford's analysis suggests that there are two independent kinds of intellectual rigidity, adaptive

flexibility, or the ability to overcome a set, and spontaneous flexibility, or the ability to produce a diversity of ideas.

3. There is evidence that stress increases adaptive rigidity or *Einstellung* rigidity. This is probably because in *Einstellung* tests the set is learned, and high drive makes learning more rapid. It would be reasonable to expect introverts to be more rigid on this sort of problem than extroverts. This type of rigidity could account for part of the decrement in intellectual performance produced by stress in introverted neurotics.

4. Spontaneous flexibility has been very little investigated.

5. If rigidity and concreteness are not identified, and both logic and experimental results suggest they should not be, there are very few experiments on intellectual rigidity in psychosis. Rigidity in psychosis will be dealt with again in the final section.

(j) Concept Formation

(i) *Concreteness*. A concept might be defined as some symbol, usually a word, used to denote a large number of stimuli. These stimuli, however, may occur in quite different stimulus compounds. In other words, the concept often denotes an attribute common to a large number of different objects.

Thinking could be regarded as the internal manipulation of concepts, and in problem-solving, the units of the problem which the hypothetical search process examines in all their permutations and combinations could themselves be regarded as concepts.

Probably most of our concepts (words, etc.) are *learned*. It is possible to regard this sort of concept formation as a process of discrimination learning. Edna Heidebreder, in an extremely interesting series of studies on normal people, has demonstrated that concepts can be learned in this way, and that even though the same stimulus compound is never given more than once, the subject ultimately learns to associate the common attributes and to use some symbol to denote them (Heidebreder, 1946*a*, 1946*b*, 1947; Heidebreder, Bensley and Ivy, 1948; Heidebreder and Overstreet, 1948; Heidebreder, 1948, 1949*a*, 1949*b*). It is not surprising to find that in children, the capacity for rote learning is highly related to vocabulary. Those who learn quickest acquire the greatest number of concepts.

Many problems merely require us to manipulate concepts we already possess (most deductive reasoning tasks). If, however, we have not learned a concept crucial to the problem, we will fail. It is hardly surprising then, that rote-learning ability is correlated so highly with problem-solving ability.

Many other problems, however, can *not* be solved merely by manipulating concepts we already possess. These tasks involve a certain amount of induction.

In other words, some new concept must be formulated to denote some common aspect of the material, and the manipulation of this concept is crucial for success.

There is a good deal of controversy about whether or not *this* type of concept formation can be regarded as a process of internal learning, or whether it is more immediate—some form of sudden recognition (“insight”). Maier (1945) favours the latter point of view. Whatever the mechanism involved, however, the inability to form new concepts would be a considerable handicap in many types of problem-solving. This inability is usually called “concreteness,” although the term is often not defined quite so specifically (e.g. Goldstein and Scheerer, 1941). Many psychologists (e.g. Goldstein, 1939*b*, 1940, 1946; Scheerer, 1946, 1953, 1954; Kasanin, 1945; Kasanin and Hanfmann, 1939) have come to regard concreteness as an important explanation of cognitive deficit, particularly in organic and schizophrenic patients.

Some of the evidence for this is derived from studies in which the Goldstein-Scheerer (1941) tests for concept formation have been used. Three of these are sorting tests. The Colour-Form test consists of a group of squares, triangles and circles of four different colours. The subject is asked to sort them into groups (form a concept) and then to resort them in a different way (form a second concept). They can be sorted for form or colour. The Object Sorting test is similar, but here a large number of everyday objects are used. The subject is asked to sort them into groups in as many different ways as he can (form as many concepts as possible). The Wool Sorting test is similar, except that the material used is skeins of coloured wool. Concepts such as “hue,” “brightness” and “saturation” can form the basis of different methods of sorting. The last two tests are ordinary performance tests. One is a block design test in which various degrees of assistance are given, and the other is a test requiring the subject to reproduce patterns with small plastic sticks (the Sticks test). It is difficult to see what the last two tests have to do with concept formation unless a very broad definition indeed is used.

Goldstein and Scheerer, while developing a standard method of administering the tests, developed no standard scoring procedure. Concreteness is rated by the examiner, and a wide range of anomalies are called concrete, including an inability to sort at all, an inability to obtain more than one principle of classification, disobeying the instructions by failing to form the objects into groups, an inability to give a very precise verbal account of what has been done and why, and so on. Goldstein and Scheerer have never demonstrated that these anomalies are related in any way, nor that the tests themselves correlate.

Bolles and Goldstein (1938) gave this test battery to a group of sixteen schizophrenics, and reported

that they were concrete. No control group of any sort was used, and it is not known how many normal people would have met their stringent criteria of an abstract performance. Hanfmann (1939*c*) reports concreteness in a single schizophrenic patient on a similar group of tests, and Cleveland and Dysinger (1944) also found that five schizophrenics were concrete on the Goldstein Object Sorting test. Again no control groups were tested.

Another group of studies makes use of the Vigotsky (1934) test of concept formation. This test consists of a number of wooden blocks of varying colours, shapes and heights. On the bottom of each block a nonsense syllable is printed. The examiner turns up the first block, and demonstrates that the name MUR is printed on the bottom. The subject is then asked to select all the blocks that can be grouped with this one. Each time an incorrect block is selected, it is turned upside down, to demonstrate that it has a different nonsense syllable on the bottom. This procedure continues until the subject correctly groups all the MUR blocks together. There are four different nonsense syllables, and four groups of blocks. The correct principle is neither colour, shape *nor* height, but volume, and the subject during the course of the test must formulate this concept. The only quantitative score used (Kasanin and Hanfmann, 1938; Hanfmann and Kasanin, 1937) is the “time-help” score, which is the number of times the examiner had to correct the subject, multiplied by five and added to the number of minutes needed to achieve the solution. This curious score obviously involves both speed of thinking and the ease with which the concept is acquired, and is necessarily ambiguous by itself.

Kasanin and Hanfmann (1938*b*) gave the Vigotsky test to fifty schizophrenics and forty-five normals of the same age. They found that the schizophrenics had significantly higher time-help scores than the normals, and that this probably was not due to educational differences.

In 1942, Hanfmann and Kasanin reported a larger study (Hanfmann and Kasanin, 1942; Kasanin, 1946) using the same test with sixty-two schizophrenics, ninety-five normal controls and twenty-four brain-damaged cases. In this study the time-help score was clearly a function of the amount of education of the subjects, but it still differentiated between schizophrenics and normals with the same education. The qualitative performance of the subjects was also rated on a variety of subjective criteria, and schizophrenics again were judged more concrete.

Fisher (1950) tested twenty normals, twenty conversion hysterics and twenty paranoid schizophrenics, using the Vigotsky test material as a sorting test to determine the number of different groupings the subjects could obtain. Normals had a mean of 16.1

(± 4.9), schizophrenics 11.3 (± 4.7) and hysterics 10.3 (± 3.9). While the normals are significantly better than the two abnormal groups, they are also brighter and considerably younger. The hysterics and the schizophrenics were not significantly different from each other.

The results using these tests of concept formation are thus almost entirely inconclusive. The Goldstein test studies are completely uncontrolled, and it is not possible to say that the Vigotsky test results were not merely due to slowness in the schizophrenic groups, since inadequate data are reported. Fisher's study certainly provides no evidence that schizophrenics are especially concrete in terms of the number of different sortings they can achieve.

McGaughran (1954) has developed a different system of scoring the Goldstein Object Sorting test. He believes that sortings can be assessed along two dimensions, a dimension of "open-closed" (conceptual freedom or concreteness) assessed by the number of objects the concept covers, and an unrelated "public-private" dimension, which is the extent to which the concept is usual or generally accepted. McGaughran and Moran (1956) administered an Object Sorting test to thirty-seven chronic paranoid schizophrenics and thirty-seven non-psychiatric hospitalized patients carefully matched for Wechsler vocabulary, educational level and age. When the test was rated in the usual way to assess concreteness, the groups were not differentiated significantly. In fact the paranoid schizophrenics were a trifle more abstract. These concreteness ratings were found to be significantly related to I.Q., as might be expected, the more abstract obtaining higher I.Q. scores. Paranoid schizophrenics however produced significantly more "private" responses and fewer "public" responses than normals. They also showed greater conceptual freedom, than the normals, incorporating more objects into their concepts, and in that sense generalizing more. Within the schizophrenic group, there was a strong tendency for private responses to be associated with a lower level of general intelligence, suggesting that the tendency to formulate unusual concepts may be a contributory factor to general cognitive impairment.

McGaughran (1957) in a further study contrasted thirty-seven schizophrenics and thirty-four brain-damaged subjects on the same test. The brain-damaged group produced significantly more "closed" (restricted) sortings, while the schizophrenics had significantly more private sortings. Again both variables correlated significantly with a vocabulary test, subjects with higher vocabulary scores having more public and fewer closed (restricted) sortings ($r = 0.42$ and -0.32 respectively).

McGaughran's series of studies suggests that schizophrenics are not concrete in the sense of being

unable to form concepts. The concepts they form do, however, tend to be unusual. Brain-damaged patients, on the other hand, *do* tend to be concrete.

A quite different method of assessing concreteness has been by the use of proverbs. A concrete response to a proverb is usually said to be one which accepts the literal meaning, and does not generalize, or re-state it in the form of a general proposition. Wegrocki (1940) tested a group of schizophrenics with a proverbs test, and found them to be more concrete than children. Benjamin (1946) produced a standard series of proverbs. He too claimed that schizophrenics are concrete, although he published no adequate data. Becker (1956) found that concreteness as rated from the Benjamin proverbs correlated significantly (-0.682 with the Elgin Prognostic Scale in a group of twenty-four male schizophrenics, but insignificantly (0.048) in a group of twenty-seven female schizophrenics.

By far the most adequate study is one by Gorham (1956). In a "pilot" study, Gorham administered a set of twelve proverbs to seventy-eight normals and one hundred and eighteen chronic schizophrenics. The answers were rated in the usual way for concreteness. The subjects were also given a set of forty proverbs in the form of a multiple-choice test. For each proverb the subject had to select one of four alternative interpretations, some of which were "abstract" and some of which were concrete. Gorham found a significant correlation between concreteness measured in this way, and a test of verbal comprehension. The schizophrenics were significantly more concrete on the sets of proverbs. In a larger study, Gorham administered the same sets of proverbs to another group of one hundred chronic schizophrenics and one hundred normals matched for age, education and word knowledge. Both an abstraction score and a concreteness score derived from the multiple-choice test differentiated the groups significantly ($p < 0.001$ in each case). The ratings of both abstraction and concreteness derived from the ordinary proverbs test also differentiated at beyond the 0.001 level. All these results were cross-validated a third time on a fresh sample of eighty-nine schizophrenics and one hundred and five normals. There seems little doubt from this large scale and carefully controlled study that schizophrenics are abnormally concrete in their response to proverbs tests.

These findings are very similar to the results obtained with vocabulary tests. This literature was reviewed in the first section, and the general finding was that if definitions of words are rated as abstract or concrete, that schizophrenics as a group tend to produce concrete definitions.

All these studies are less than conclusive, however. There is little doubt that schizophrenics define words and interpret proverbs peculiarly. Their unusual use

of language has been demonstrated objectively in other studies using different techniques (Ellsworth, 1951; Mirin, 1955). It is conceivable that this abnormality could be due to their inability to form new concepts. However there are equally probable alternative explanations. For example, curious definitions of words and proverbs could indicate not an inability to form new concepts, but a tendency to form *different* or unusual concepts. This would be more in keeping with McGaughran's results (McGaughran, 1954, 1957; McGaughran and Moran, 1956). It is also conceivable that, just as they tend to use and define words unusually, some schizophrenics may *interpret* words they hear unusually. They may misunderstand what they are told. Some schizophrenics may, for instance, interpret the instructions of the proverbs test as allowing either a general statement of the principle illustrated *or* the use of an apt (by their definition) concrete illustration of the meaning of the proverb.

A careful analysis of the use of language in schizophrenia has formed the basis of most psychiatric studies of thought disorder (Bleuler, 1950, 1951; Schneider, 1930). While these methods yield fruitful hypotheses, the hypotheses must be tested by more direct experiments. A conclusive answer can only arise from a study in which schizophrenics are actually required to form new concepts, and their ability to do this is assessed.

There are several studies which attempt to assess concept formation more directly. Rashkis, Cushman and Landis (1946) developed a test similar to the object sorting test, except that the "objects" to be sorted were words printed on cards. These had to be placed in blank squares on a large sheet of paper. Some of the squares already contained key words. The test, in fact, required the subject to build up a sort of "concept matrix" with the cards, the rows referring to different concepts. Afterwards, the subjects were required to verbalize their concepts, and then to shift by sorting all the cards differently. Results were obtained from nine children, eight schizophrenics, ten general paretics and nine normal adults. Only the normal adults performed the test perfectly. The paretics could attain no complex organization at all. The schizophrenics formed concepts but they were eccentric and unlike those used by the normals. These results are very similar to those reported by McGaughran and Moran (1956).

Rashkis (1947) reported a second, similar experiment. The same word sorting test was used, and a number sorting test was added. The subject was given numbers printed on cards, and required to complete a square matrix in which key numbers had been entered, and which also contained addition signs and equality signs—a sort of numerical "crossword puzzle." Ten schizophrenics, ten general paretics and ten arterio-

sclerotics were tested. The schizophrenics were best at both tests.

Feldman and Drasgow (1951) developed a test consisting of a set of cards. Each card pictured four objects in a row. For example, card 1 contained four circles. Three were large, and one small, and one of the large circles was coloured black. Three of the objects could be grouped together for one reason (e.g. all the large circles on card 1), but another group of three objects could be formed for another reason (e.g. all the white circles on card 1). Feldman and Drasgow gave the test to thirty-seven early schizophrenics and thirty-seven normals matched for age and education. The number of "single misses" (missing one of the two concepts) differentiated the groups at the 0.0001 level of significance, while the number of "double misses" (missing both concepts on a card) differentiated even better. All the schizophrenics had eight or more double misses while all the normals had seven or fewer double misses. These results are not unambiguous however. Schizophrenics could get poor scores either because they are unable to induce a concept at all (are concrete) or because they formulate an unusual concept which produces an unusual answer. The latter possibility must be taken seriously in view of the findings already discussed.

It is interesting that Payne, Matussek and George (1959) were unable to repeat Feldman and Drasgow's findings, on a small group of fourteen schizophrenics and thirteen neurotics, using a similar test scored identically. The groups were not differentiated significantly in terms of the total number of errors (and failures). The neurotics had slightly fewer double misses, but the difference was not significant. A one-minute time limit per card (as used by Feldman and Drasgow) was shown to have no influence on the results as the scores with and without the time limit were not significantly different.

A more satisfactory technique for investigating concept formation in abnormal subjects is the Wisconsin Sorting Test (Berg, 1948; Grant, Jones and Tallantis, 1949; Grant, 1951). This test is very similar to Heidebreder's technique for studying concept formation in normals. The test is composed of sixty-four cards. These have to be sorted one at a time with one of four stimulus cards. Each time the subject sorts a card, he is told "right" or "wrong." The first principle of sorting is based on colour. When the subject places ten cards consecutively with the correct stimulus card the principle is changed to "form." When the same criterion is reached for the second principle, it is changed again and the procedure continues. The test demands five shifts in all. The test is over when all the sixty-four cards are sorted *or* when all the concepts have been learned, whichever is first. Fey (1951) administered this test to twenty-two

young schizophrenics and forty-seven young normals matched for age, tested intelligence, education and sex. Sixteen of the twenty-two schizophrenics failed to complete the test successfully, while only eight of the forty-seven normals failed. The schizophrenics who succeeded made more errors than the normals who succeeded. The correlation between success and I.Q. was insignificant in both groups. The overall performance on this test is unfortunately a function of both the ability to learn a concept and rigidity. The results would be more clear-cut if data had been reported on the number of trials needed to learn the *first* concept. There is, however (as will be discussed later), no reason for supposing schizophrenics to be abnormally rigid in this sense, so that some abnormality of concept formation is highly probable. Fey suggests that the schizophrenics obtained poorer scores not through difficulties in "initial" learning, but because they "seemed to experience more difficulty in holding the correct set, once having achieved it . . ." She also reports that when the groups were asked to *explain* the concepts, both normals and abnormals gave equally concrete explanations.

These studies then suggest that schizophrenics as a group are probably not abnormally concrete in the sense of being unable to form a new concept. They are, however, abnormal in the *type* of concepts they form. Their concepts tend to be unusual and often eccentric. They are able to learn normal concepts, but tend to have difficulty in adhering to them when asked to employ them over a period of time.

There are remarkably few studies of concept formation in other disorders, particularly in the affective psychoses. Tong (1955) administered a sorting test to one hundred and sixty-one prison inmates. Some of the subjects failed to obey the instructions, and made patterns with the material instead of sorting it into groups. Slightly more of those who patterned than those who did not, were judged to be psychotic or brain-damaged.

Payne and Hewlett (to be published) in a study already referred to, administered a large number of tests of "overinclusive thinking," psychomotor, mental and perceptual slowness, and a number of miscellaneous measures to carefully-matched groups of twenty schizophrenics, twenty depressives, twenty neurotics and twenty normal people. Five measures of concreteness were also included. These were concreteness ratings derived from the Goldstein Colour-Form and Object Sorting tests, a concreteness rating derived from the Benjamin Proverbs test, and abstraction scores derived from an object classification test and the Shaw test of concept formation. It was predicted that the schizophrenics would be rated more concrete on the two Goldstein tests and the Proverbs test when the traditional criteria were used because unusual

generalizations tend to be rated as concrete. This was the case for all three measures. The depressives were no different from the normals and neurotics on these three ratings. However, neither of the two abstraction scores produced significant differences between any of the groups. The entire battery of tests was intercorrelated and factor-analysed for the combined group. It was demonstrated that, as expected, the concreteness ratings from the Goldstein tests and the Proverbs test were loaded on a factor labelled "over-inclusion." Factor scores of overinclusion significantly differentiated the schizophrenics from the other three groups, only schizophrenics being abnormal in this respect. Again this was consistent with the hypothesis that schizophrenics are rated as concrete merely because of their usual (overinclusive) generalizations. A factor labelled "general intelligence" was derived from the factor analysis. Factor scores for general intelligence did not differentiate the groups significantly. This was as expected, because the groups had been carefully matched for pre-illness level, and were not significantly different on the Nufferno "Level" test. All five measures of concreteness had very high loadings on this general intelligence factor (ranging from 0.57 to 0.83). It was suggested that concreteness as measured by these tests is mainly a measure of general intellectual level, although the concreteness ratings from the Goldstein tests and the Proverbs test are also affected by overinclusive thinking to some extent. It was concluded that there was no evidence that either of the two psychotic groups were concrete in the sense of being unable to produce abstract generalizations.

While an inability to develop new concepts as such is probably *not* a characteristic of any particular functional diagnostic group, it is possible that some individuals are abnormal in this respect. Several studies have investigated some possible causes of abnormal concreteness and some ways of altering it. Beier (1951) studied the effect of stress on concreteness. Sixty-two student teachers were given an abstract reasoning test and a test requiring them to formulate abstract explanations for groups of objects presented to them. A group tested under stress did worse than a group tested under normal conditions. It is not clear, however, whether the stress made them more rigid or whether it impaired their ability to form concepts.

Cohen, Senf and Huston (1954) gave a sorting test to a group of twenty-four chronic schizophrenics, twenty-two early schizophrenics, twenty-one depressed patients and twenty-one neurotics. The groups were not matched. Under normal conditions, the chronic schizophrenic group and the early schizophrenic group both produced "vague categories" and "chain associations." The depressives and the neurotics both produced more satisfactory categories, there being no

differences between them. The groups were then retested under "affective conditions." Four common test objects were replaced by any four objects believed to be particularly emotionally disturbing to the individual patient. The normal test was repeated under the influence of Sodium Amytal, and finally the affective test was repeated under amytal. The drug by itself had a significant overall effect. All the subjects finished the test more quickly, especially the depressives who had initially been the slowest group. The drug reduced the quality of the answers given by the depressives, but improved the neurotics. The schizophrenics did not change. The affective condition of test administration by itself changed only the depressives, making their responses poorer. The affective conditions plus the drug made *all* the groups worse, the schizophrenics showing the greatest decline. For all the groups combined, the sorting test correlated + 0.34 with general intelligence.

This study suggests that an increase of affect, particularly when assisted by Sodium Amytal, may cause patients, and particularly psychotics, to become more vague in their concept formation, possibly due to the fact that these emotions have a distracting effect.

It is clear that a gross defect of rote learning could produce an inability to form new concepts, as most concept formation could be regarded as discrimination learning. As one might expect, there is some evidence from sorting tests (Inglis, 1958) that old people, and especially patients with senile dementia are abnormally concrete in the sense of being unable to sort at all. These studies are not as conclusive as it might appear, however. While *most* concepts are learned, the concepts which are "induced" in response to sorting tests are developed very quickly, and correspond better to the sort of concept formation described by Maier (1945) as *not* learned but immediately apprehended in some way. It is also rather anomalous that many of the concepts actually induced in these sorting tests are ideas like "size," "weight," or "colour." It is clear that old people must have learned, for example, the concept of size in the past. It is odd then, that they are unable to use such concepts to sort objects. The only reasonable explanation would seem to be that the *sorting test objects* were never incorporated into these learned concepts, because the test represents a new experience. In other words, *learned* concepts include *only* those "items" from which the concept has evolved. They do *not* extend to similar but entirely novel stimulus compounds. This is, in fact, quite compatible with the discrimination learning explanation for such concepts. It follows, however, that the extension of concepts into an entirely new situation may not be a process of learning at all, but some immediate "recognition." It is a failure in this second sort of concept formation

which causes the elderly to fail at sorting tests. As they *also* have learning defects, the implication is that they are poor at *both* types of concept formation, although the *cause* of their failure to "perceive" non-learned concepts is left unexplained.

The above studies suggest at least one possible cause of concreteness. There are also a few articles reporting investigations into other abnormalities which might be associated with abnormal concreteness. Rokeach (1951), assessing concreteness in one hundred and forty-four normal subjects by their ability to define words like "Buddhism" and "Capitalism" found that concreteness was correlated with ethnocentrism. Since intelligence was also correlated with ethnocentrism, however, the results are not conclusive. Mathews *et al.* (1953) found that among normal subjects, those more concrete on a sorting test tended to get higher "Pd" and "Ma" scores on the M.M.P.I. However, this could merely be another demonstration of the fact that extraverts tend to be duller than introverts.

Flavell (1956) gave a multiple-choice vocabulary test to twenty-four schizophrenics. They produced more concrete definitions than a normal group. There was a correlation of 0.60 in the schizophrenic group between the number of abstract responses and a measure of social interaction. The study suggests that schizophrenics with the most unusual concepts tend to be the least sociable, perhaps because they find communication with other people more difficult. It is interesting that Gollin and Rosenberg (1956) reported a similar finding for normal people. On the Rokeach test of concept formation, those who had high scores (were able to form concepts) tended to be less extreme in their social distances as assessed by a questionnaire.

(ii) *Overinclusion.* Norman Cameron (1944, 1947; Cameron and Magaret, 1951) has performed a number of investigations into the nature of concept formation in schizophrenia. In 1938 Cameron (1938a) administered an "incomplete sentences" test to twenty-five schizophrenic patients. He also (Cameron, 1938b) tested twenty-two patients with senile psychosis, twenty-nine normal children, and twenty normal adults. From an analysis of the way in which the subjects completed these sentence fragments, he concluded that schizophrenic's thought disorder is not a form of regression, as their sentences were unlike those of children. Their sentences were also unlike those produced by patients with senile dementia. The schizophrenic sentences had several peculiar characteristics, the most important of which he later attributed to overinclusion and the interpenetration of personal themes. In a further study Cameron (1939a, 1939b) gave the Vigotsky test to five of the most severely disorganized schizophrenics in the original group, and six of the most disorganized senile patients.

He concluded from a qualitative analysis of this material that the senile patients were unable to grasp the nature of the problem, and were rigid. The schizophrenics were not rigid. They showed, however, the same peculiarities of concept formation as those noted earlier. Their thought was distracted by the interpenetration of personal themes. They were also overinclusive. Cameron defines overinclusion as the inability to preserve conceptual boundaries. Ideas associated with, or distantly related to, concepts become incorporated into them, making them both more abstract and less precise. In the solution of a problem the schizophrenics "included such a variety of categories at one time that the specific problems became too extensive and too complex for a solution to be reached" (Cameron, 1939a).

A disorder of concept formation of this sort has been described by other writers such as Schilder (1954), Bychowski (1943) and Angyal (1946). Lovibond (1954) perhaps gives it the clearest general formulation.

Most concept formation can be regarded as a form of discrimination learning. For example, when a word is first heard in a certain context, it first comes to be associated with the entire situation ("stimulus compound"). As the word is heard again and again, only certain aspects of the stimulus compound are reinforced however. Gradually the extraneous elements cease to evoke the response (the word), having become inhibited through lack of reinforcement. This inhibition is in some sense an active process, as it suppresses a response which was formerly evoked by the stimulus. It is possible to imagine a disorder of the process whereby inhibition is built up to circumscribe and define the learned response (the word or concept). This disorder would result in overinclusion in the formation of the concept, and could be regarded as an extreme degree of stimulus generalization. We will use the term overinclusion for this postulated abnormality, although Cameron sometimes uses the term in a wider sense.

It is conceivable that when this abnormality develops (through some form of psychosis), concepts which are learned after the acquisition of the abnormality are the first to become affected, but that, gradually, recently acquired concepts, and, finally, older concepts are affected as the process of inhibition becomes weaker.

A number of studies have been reported which support the hypothesis that the main abnormality of concept formation responsible for the observations so far discussed, is abnormal overinclusion.

In 1948 Shneidman developed the Make-a-Picture-Story test, in which subjects are required to select human figures from a large group, place them on a background card (different backgrounds are used picturing outdoor and indoor settings) and then make up a story about the scene created. He administered

it to a group of fifty schizophrenics (72 per cent paranoid schizophrenics), and fifty normals. Among other differences in performance noted, the schizophrenics tended to use an abnormally large number of figures in their pictures. They seemed unable to restrict their attention to a few figures relevant to a simple theme. Balken (1943) similarly observed on the T.A.T. that schizophrenics tend to produce rather diffuse stories.

Zaslow (1950) developed a simple test to measure overinclusion. It consisted of fourteen cards. Card 1 depicts an equilateral triangle, and card 14 a perfect circle. In the intervening cards, the shape gradually changes from a triangle to a circle. In one part of the administration procedure the examiner places the cards in order, and asks the subject to indicate where the circles end, and where the triangles end. Zaslow predicted from Cameron's theory that schizophrenics would include more cards in each concept. The results obtained from twenty-four schizophrenics and sixteen normal surgical cases supported the hypothesis. Kugelmass and Fondeur (1955) repeating the study on forty-five early schizophrenics, twenty-three acute schizophrenics and twenty-three normals, failed to confirm these results at an acceptable level of significance. They found, however, that the test-retest reliability was so low as to be insignificant for some scores.

White (1949) tested twenty schizophrenics and twenty normals carefully matched for age, sex, education and background. They were given fifteen words printed on cards to group in any way they wished. The schizophrenics tended to form very large, vague categories, forming concepts such as "suspicion" or "having to do with God."

Daston, King and Armitage (1953) read two short stories aloud to twenty-five paranoid schizophrenics and twenty-seven matched normals. Afterwards the subjects were given a check list of thirty-six positive and thirty-six negative statements about the characters in the stories. The schizophrenic group checked off significantly more adjectives than the normals.

Moran (1953) tested several deductions from Cameron's theory on a group of forty schizophrenics and forty normals carefully matched for age, sex, vocabulary score and occupational level. The subjects were first given twenty-five words to define. There were no differences in the conceptual level of the definitions given, thus the hypothesis that "schizophrenics" are concrete was not supported. The subjects were then asked to give as many synonyms as possible for each word. As predicted from Cameron's theory, the schizophrenics gave more imprecise synonyms. The subjects were then given a test in which each word (printed on a page) was followed by eight response words, including neologisms. Some

response words were an essential part of the concept denoted by the stimulus word, and some were words which were more or less associated. The subjects were asked to underline every word which they regarded as an essential part of the concept denoted by the stimulus word. As predicted, the schizophrenics did *not* underline significantly fewer correct words, but did underline significantly more of the distantly related words. When asked to free associate to the words, the schizophrenics produced more distant associations. When asked to incorporate the words into a sentence, their sentences were unclear, contradictory and ungrammatical. When the words were incorporated into a similarities and an analogies test, the schizophrenics produced significantly inferior performances. This study suggests strongly that the poor scores obtained by schizophrenics on such tests as similarities and analogies can be attributed to an overinclusive definition of the concepts involved.

Epstein (1953) developed a verbal test of over-inclusion using a method very similar to that of Moran. Fifty stimulus words are each followed by six response words including the word "none." The subject is asked to underline all the response words which he considers a necessary part of the concept denoted by the stimulus word (or the word "none" if all are unnecessary). As predicted, a group of schizophrenics underlined significantly more words than a matched group of normals with the same level of vocabulary.

Rapaport *et al.* (1945), using an object sorting test, found that a group of schizophrenics were no more concrete than a group of normals. They did, however, tend to form more vague syncretistic concepts. Lovibond (1954) administered the Goldstein Object Sorting test to thirty-two schizophrenics and forty-five matched normal controls. He employed an elaborate rating system to assess the amount of overinclusion or failure in inhibition, which occurred in the sortings of the two groups. The scores differentiated significantly as predicted from Cameron's hypothesis.

An ingenious series of experiments by Chapman (1956) and Chapman and Taylor (1957) have provided the most convincing tests of the overinclusion hypothesis. Chapman (1956) investigated a group of forty schizophrenics and twenty-five matched normals. The subjects were shown three stimulus cards which had a picture or a symbol in each of the four corners. The subjects were asked to group a series of similar response cards with the relevant stimulus card. They were told to disregard *all* the pictures on the stimulus cards except the picture in the lower right-hand corner. A response card which contained anywhere among its four pictures an identical picture, or one of the same sort, as a stimulus card, was to be grouped with that stimulus card. Sixty response cards in all were used.

Response cards had varying numbers of items on them matching *irrelevant* items on the stimulus cards. It was predicted that the errors in the schizophrenic group would be produced by these distractor items. The results were exactly as predicted. Response cards with *no* distractor items did not differentiate the groups, normals and schizophrenics making an equal number of errors. Furthermore, as predicted, there was a strong relationship between the *number* of distractor items per card, and the number of mistakes made by the schizophrenic group. There was no such relationship within the normal group, all cards producing an equal number of errors. The schizophrenics' performance was not due to forgetting, as their errors did not increase during the test. The number of failures on this test within the schizophrenic group was correlated with a rating of severity of illness.

Chapman and Taylor (1957) in another experiment, investigated twenty-four mildly disturbed schizophrenics, twenty-four severely disturbed schizophrenics and twenty-four normals matched for age and education. As might be expected, the schizophrenic groups had lower tested I.Q.s. (It is obviously not desirable to match groups for present I.Q. since this is controlling for the disability one is seeking to explain in the experiment.) The subjects were given the name of a concept (e.g. fruit) and were asked to sort a number of cards, each bearing the name of a specific item (e.g. "apple," "fish"). Some of the cards bore the names of specific fruits, and therefore should be grouped in the "fruit" category. An equal number of cards bore the names of similar, but incorrect items (e.g. the names of vegetables). A third group of cards bore the names of quite different objects (e.g. birds). It was first predicted that the schizophrenics would overinclude by including the similar items (vegetables) with the correct items (fruits). The results were exactly as predicted. The normals made virtually no errors, while the schizophrenics included a significant number of similar cards incorrectly. There was no evidence for concreteness however, as the schizophrenics, like the normals, did not include the *dissimilar* cards. The two schizophrenic groups were not differentiated by the test. The test successfully differentiated between a group of normals and a group of schizophrenics matched for I.Q. In a second experiment, there was no evidence for abnormal "underinclusion" (the tendency to be abnormally restrictive in concept formation) in the schizophrenic groups.

These studies produce remarkably consistent results, which strongly support the hypothesis that schizophrenics display abnormal overinclusion in their concept formation.

It is conceivable (as Lovibond, 1954, has suggested) that overinclusion is only one aspect of a more general abnormality. Certainly one further prediction can be

made from the hypothesis. In tests of adaptive rigidity, such as the Luchins test of *Einstellung* rigidity, a "set" is probably produced by the same process of discrimination learning believed to account for some concept formation. As some types of solution are consistently not reinforced, they become inhibited. Later, when the subject would find these solutions useful, he is "blinded" to them by the set he has developed. If schizophrenics are abnormal in their inability to develop this sort of inhibition, they should find it difficult to develop a set of this sort. This could be either an advantage or a disadvantage, depending on the sort of problem. They should, for example, be better at doing the Luchins *Einstellung* rigidity test. In fact, if this hypothesis is correct, schizophrenics should show an abnormal amount of adaptive flexibility. This prediction was tested by Payne and Hewlett (to be published), who compared twenty schizophrenics with a combined group of twenty normal, twenty neurotics and twenty depressives on a modified form of the Luchins *Einstellung* test. The schizophrenics were significantly less rigid following the establishment of the set.

Angyal (1946) seems to have been one of the first writers to suggest that schizophrenics are abnormal in their relative inability to develop a set. There are some other results consistent with this hypothesis. White (1949) investigated a group of twenty schizophrenics and twenty normals. The subjects were given a number of words printed on cards to read. Some were clearly printed, but some were so blurred that they were impossible to read (they were reproductions of very poor carbon copies). The subjects were told to guess what was on each card. On only three out of three hundred occasions, did any normal subject fail to give some word as a guess. Schizophrenics fairly frequently said that they did not know what was on the card, or tended to guess things other than words (e.g. "teeth" or "spots"). Presumably the normals, after seeing the first clear word, rapidly developed a set to perceive words whatever the card looked like, and failed to perceive the true nature of the stimuli. In a second experiment, the subjects were asked to make up sentences using the words. The normals, perhaps due to a preconceived set about what was required, never used the same sentence twice, and never used grammatically incomplete sentences. The schizophrenics frequently did both these things.

Payne, Matussek and George (1959) performed a different sort of experiment on a group of eighteen schizophrenics and sixteen neurotics. The subjects were shown a piece of paper on which circles containing letters or numbers were printed at random. Without verbal instructions, the examiner connected them with a pencil in the order 1—A—2—B, etc., numbers and letters alternating. The subjects were then given an

identical sheet of paper, and motioned to do the same. No subjects made errors. Finally they were presented with a sheet of paper on which was printed many more circles containing letters and numbers, but this time in a quite different arrangement. Again the subjects were motioned to proceed. It was predicted that the neurotics would have no difficulty, since they would come into the test with a strong set that numbers and letters should be arranged in order. The first part of the test would confirm this set and they would subsequently completely ignore the other aspects, such as the spatial juxtaposition of the letters and numbers. Schizophrenics, on the other hand, should tend *not* to develop this set. In the final part of the test they should notice the altered arrangement of the letters, and the more complex and detailed explanation of the examiner's performance they had probably formulated during the first part of the test would no longer apply, since the same relationship between letter-number sequence and spatial arrangement no longer applied. It was predicted that in this conflict situation they would take very much longer, and would probably make a number of errors. Both predictions were verified significantly. The neurotics made an average of only 1.86 errors, while the schizophrenics made an average of 7.00 errors.¹ The two groups were also shown to differ significantly in overinclusion on the Epstein (1953) test. The schizophrenics were also more overinclusive in a measure derived from the Goldstein Object Sorting test. During the "handing over" part of this test (when the subjects are asked to select all the objects they would group together with a given object) the schizophrenics grouped together significantly more objects than did the neurotics.

It is possible to formulate the hypothesis of overinclusion in a more general way, so that it accounts for a number of other findings. All purposeful behaviour depends for its success on the fact that some stimuli are attended to and other stimuli are ignored. It is a well-known fact that when concentrating on one task, normal people are quite unaware of most stimuli irrelevant to the task. It is as if there were some filter mechanism (to use an information theory term) which cuts out those stimuli, both internal and external which are irrelevant to the task in hand, to allow the most efficient processing of incoming information. Many schizophrenics behave as if this filter had lost some of its inhibitory properties, and allowed irrelevant information to enter the processing mechanism. Abnormal intellectual slowness in some psychotics may well be due partly to this abnormality. Normal people only consider a certain amount of information as being relevant to the problem. Some psychotics

¹ The material used in this experiment was taken from the Leiter-Partington "Pathways" test. (Leiter and Partington, 1950.)

whose thought processes may be just as fast, might have more possible solutions to consider because they fail to exclude certain data which normal people judge to be irrelevant.

If this is the case, a number of predictions can be made. In a sorting test of inductive reasoning which has a large number of possible solutions, given no time limit, schizophrenics should be able to achieve many more solutions merely because they do not arbitrarily ignore some of the data as irrelevant, and are able to base extra methods of sorting on these additional aspects of the material (e.g. the unintentional scratches on the objects, their cleanliness, the shadows cast by the objects on the table, their personal associations to the objects, and so on). If schizophrenics are not essentially slow in thinking, they should be able to produce responses just as frequently as normals. They should however take much longer over the test, merely because they produce many more methods of sorting. They should present normal and abnormal sortings in a completely random order, because they should not distinguish between sortings based on relevant and sortings based on irrelevant aspects of the material.

Payne, Matussek and George (1959) verified some of these predictions on eighteen schizophrenics and sixteen neurotics. The sorting test used was a modification of Goldstein's Object Sorting test. The objects were squares, triangles and circles which varied in size, weight, thickness, density, material, and the hue, brightness and saturation of the colours. There were ten rational ways of sorting the objects. The schizophrenics obtained an average of 11.66 different methods of sorting, both rational and bizarre. The neurotics produced an average of only 7.07 methods of sorting. It is clear from these results that schizophrenics cannot be regarded as either concrete or rigid in the usual sense of the terms. In fact they are abnormal in their degree of spontaneous flexibility.

Payne and Hewlett (to be published) administered the same test to matched groups of twenty schizophrenics, twenty depressives, twenty neurotics and twenty normal people. As expected, the groups did not differ significantly in the number of rational responses, producing no evidence for abnormal concreteness in any of the groups. However, the schizophrenics produced many more unusual methods of sorting the material than did the other groups, and hence had a larger total number of responses. Similar results were obtained using the Shaw test of concept formation.

It is not surprising, if this hypothesis is accepted, that schizophrenics are original in their responses to word association tests, and that they do not adhere to the prohibitions which normal people assume are intended.

This general inability to develop an inhibitory set can account for some apparently diverse findings which have been reported. For example, Rodnick and Shakow (1940) attributed schizophrenic slowness and variability in reaction-time to an inability to maintain a set. (Huston and Senf, 1952; Huston and Singer, 1945; Knehr, 1954.) Pascal and Swensen (1952) found that when a very loud distraction is used, reaction-time measures no longer differentiate schizophrenics from other groups. (Presumably because all the groups are then equally distracted.) Venables (1958) reports a possible confirmation of this interpretation. He gave a multiple-choice reaction-time test in which the number of stimuli were varied from one to eight, to a group of normals, and a group of paranoid schizophrenics. When the relationship between the "bits" of information conveyed at each difficulty level, and reaction-time was examined, the curves suggested that the schizophrenics reacted at each level precisely as if the lights conveyed more information for them than for the normal subjects. That is, they reacted as if they were performing a more complex discrimination than the normals. This could possibly be because they have not only to distinguish between the lights, but also between the lights and the irrelevant stimuli they are unable to inhibit, or filter out. There is, however, one set of results which is difficult to reconcile with this hypothesis. Payne, Matussek and George (1959) found that a group of eighteen schizophrenics were neither significantly slower nor significantly more variable on a simple visual reaction-time test than a group of sixteen matched neurotics, although these same schizophrenics were significantly more overinclusive on a number of tests of concept formation than were the neurotics.

Most of the data so far discussed were derived from experiments on schizophrenics. There was no evidence that endogenous depressives are not equally overinclusive. Thus overinclusion might be an abnormality common to all psychotic patients. Indeed, Payne and Hirst (1957) in a small study found that eleven cases of endogenous depressives were significantly more overinclusive on the Epstein test than a matched group of fourteen normal people.

Payne and Hewlett (to be published) conducted a large scale study partly to determine whether overinclusion was an abnormality common to all psychotics, or specific to schizophrenics. A carefully matched group of twenty schizophrenics, twenty endogenous depressives, twenty neurotics and twenty normal people was given a number of tests of overinclusion, slowness (mental, motor and perceptual), and concreteness, along with other miscellaneous tests. In all twenty-three measures of overinclusion were obtained. Of these, thirteen were regarded as relatively "pure" measures, uncontaminated by other

factors. The remainder were thought also to be measures of general psychomotor slowness. The tests from which these measures were derived included the Benjamin Proverbs test, the Goldstein Object Sorting test, the Shaw test, an object classification test, the Epstein test, the Luchins *Einstellung* test, and the Leiter-Partington Pathways test. All the measures of overinclusion produced mean differences in the expected direction. Only the schizophrenics had high (overinclusive) mean scores, the other three groups having very similar means. For the thirteen theoretically "pure" measures of overinclusion, six of these mean differences were significant.

All the tests for the combined group were inter-correlated and factor-analysed. It was predicted that the factor of overinclusion should be that factor which maximized the differences between the schizophrenics and the depressives. Such a factor was obtained by a suitable rotation in conjunction with a discriminant function analysis, and it was shown that the eight highest loadings were obtained by tests regarded as "pure" measures of overinclusion. Of the twenty-three measures of overinclusion, only four produced loadings on the factor opposite to prediction, and these were very small loadings indeed. Factor scores were computed for this overinclusion factor, and it was shown that schizophrenics were significantly more overinclusive than the other three groups, there being no significant differences between the depressives, the neurotics and the normals.

A factor labelled "retardation" was also obtained. This factor discriminated significantly between the combined psychotic group, and the combined normal and neurotic group, the psychotics being slower. There were no differences between the schizophrenics and the depressives, nor between the normals and the neurotics. The highest ten loadings on this factor were obtained by speed scores, and of the twenty-five loadings greater than ± 0.30 , only six were not obtained by speed scores. This factor was a general factor of retardation, tests of mental, motor and perceptual slowness tending to have equally large loadings.

The correlation between the factor of retardation and the factor of overinclusion was -0.38 . This was consistent with the hypothesis that an abnormal degree of overinclusion tends to produce slowness of thinking, presumably because overinclusive individuals have more data to think about for any given problem.

The third factor obtained was labelled general intelligence. It did not differentiate any of the groups significantly as they had been matched for pre-illness level.

This study suggested that the endogenous depressives, as a group, were abnormally retarded, but not

overinclusive. They were relatively homogeneous with respect to retardation.

The schizophrenics, on the other hand, were extremely heterogeneous on both measures. While on average they were as retarded as the depressives, a large proportion was within the normal range, while a large proportion was more retarded than the average depressive. Similar results were obtained on the factor of overinclusion. Only about half the schizophrenics were abnormally overinclusive. Half were within the normal range, both on the factor score and on the individual tests. Half were completely outside the normal range. Schizophrenics' scores thus ranged from the most normal scores obtained, to the most abnormal scores obtained, on nearly all the measures of overinclusion. These results are consistent with most of the other studies reviewed. It is a common finding that schizophrenics as a group are extremely heterogeneous.

Payne and Hewlett concluded that schizophrenics should not be regarded as representing a single group. They suggested that there might be two groups of schizophrenics. One resembles the endogenous depressives, in that it is not abnormally overinclusive. Like the depressives, these schizophrenics are abnormally retarded. Indeed they are even slower than a depressive group. The reason for their abnormal slowness is obscure. It would be extremely interesting to discover what symptoms are found in this group. It is possible that these patients might show catatonic features and inappropriate affect (*see* Harris and Metcalfe, 1956); and might have a poor long-term prognosis.

The second group of schizophrenics are quite unlike depressives. They suffer from an abnormal degree of overinclusion. While they are slightly retarded, their slowness is merely due to their abnormal overinclusion, which causes them to over-elaborate most tasks, and thus take longer to do them. As a group, their speed scores are nearly all within the normal range. It is interesting to speculate what pattern of symptoms might be associated with this pattern of cognitive abnormality. It is tempting to relate overinclusion to paranoid delusions, and ideas of reference. Both these symptoms could be regarded as unwarranted generalizations from the facts. Patients with these symptoms often tend to perceive relationships where none exist, and to take as evidence for their views data which most people would not notice, or judge to be irrelevant (e.g. certain gestures). Payne and Hewlett (to be published) found that in their schizophrenic group, the two most overinclusive individuals, as judged by test scores, had been diagnosed as a paranoid schizophrenic, although they did not attempt to relate symptomatology to test scores systematically because of the small numbers in each group. It is possible that this

group of schizophrenics suffers little general deterioration, and has a better long-term prognosis. Indeed, what general deterioration it demonstrates may be due solely to overinclusive concept formation.

It has been suggested that overinclusion is due to an abnormal degree of stimulus generalization. Mednick (1958) has independently formulated the same hypothesis, and has suggested that this might be due to an abnormally high drive level. Whatever the underlying cause, several studies have found evidence consistent with an abnormal degree of stimulus generalization in early schizophrenics (Garmezy, 1952; Bender and Schilder, 1930; Mednick, 1955). Carson (1958) failed to confirm these earlier findings, but none of these authors have attempted to relate stimulus generalization to any specific pattern of symptoms. Differences between the schizophrenic groups tested could account for such discrepancies. So far, no attempt appears to have been made to investigate the relationship between specific tests of overinclusion, and stimulus generalization gradient.

Summary and Conclusions

1. There is no evidence that schizophrenics or any other functional psychotic groups are abnormally concrete, or unable to form new concepts, although elderly demented patients are concrete in this sense.
2. Some schizophrenics may, however, have difficulty in adhering to new concepts when asked to employ them over a period of time.
3. There is considerable evidence that some schizophrenics form unusual and even eccentric concepts, and

that this abnormality is related to their low scores on tests of general intelligence. It is also associated with the severity of the illness, and with a lack of sociability, perhaps because it makes communication with others difficult. This abnormality can probably be exaggerated by a strong emotional disturbance, perhaps because of the distracting effect.

4. Some schizophrenics employ abnormally overinclusive concepts in the sense that they incorporate ideas which for normal people are only peripherally related, or irrelevant. Overinclusion makes their thinking both more abstract and more vague. It may be due to a specific learning disability, an abnormal degree of stimulus generalization perhaps caused by a defect in the ability to develop inhibition.

5. These abnormalities of concept formation may partly explain why some schizophrenics tend to make an abnormal number of errors on cognitive tests.

6. Overinclusion might be regarded as some failure of the mental filter mechanism which excludes stimuli which are irrelevant to the action of the moment. This could partly account for cognitive slowness in some schizophrenics, which could be due to the fact that these individuals consider aspects of cognitive problems excluded as irrelevant by normal people. This same abnormality might be the direct cause of the abnormal flexibility (both adaptive and creative) and originality of some schizophrenic patients.

7. It is not known what specific symptoms are related to abnormal overinclusion. It is conceivable, however, that it is responsible for the development of paranoid delusions and ideas of reference.

GENERAL SUMMARY AND CONCLUSIONS

It is difficult to produce a short comprehensive summary of the numerous facts and interrelationships which have been discussed. This summary is an attempt to bring together some of the main findings in a more integrated, but much more speculative form. The main difficulty throughout is that we have been forced to sidestep the central issue. There is no general theory of cognition, and those facts which were easiest to integrate and explain turned out in the main to be related to essentially non-cognitive processes like learning.

Problem-solving in normal people involves a number of probably independent processes. Perception is involved in the recognition of the data of the problem. Memory span is required to hold certain facts in mind temporarily while they are manipulated. Learning, with all its parameters, influences both the immediate ability to memorize additional vital facts too numerous for span of attention to incorporate and the ability to remember past experiences relevant

to the problem. It has even produced the concepts according to which the data are manipulated. At this point, however, cognition occurs. In some way, all these data are processed and an answer results. New concepts may spring suddenly to mind to assist this in a manner quite unexplained. People vary in the speed with which this processing occurs, in the accuracy of their answers, and in the time they are willing to devote to the task. Exactly how it is done, and what produces the error has never been satisfactorily explained.

Several apparently unrelated abnormalities seem to produce different "constellations" of cognitive abnormalities. Perhaps the most basic of all is a disorder of perception. This can interfere with the whole process from the very beginning, since the data of the problem are not obtained correctly. Errors in solution are therefore likely to occur. What causes this perceptual disability is not known, but it seems common in psychosis. It may be related to other misperceptions

such as hallucinations, unreality feelings or even feelings of depersonalization.

An equally serious, but perhaps quite unrelated abnormality also occurs sometimes with psychosis. The mechanism of attention itself seems to become defective. Whatever filtering mechanism ensures that only the stimuli (internal or external) that are relevant to the task enter consciousness and are processed, seems no longer able to exclude the irrelevant. This has numerous repercussions. Thinking becomes distracted by external events. It also becomes distracted by irrelevant personal thoughts and emotions which may even become mixed up with the problem. Selective perception becomes impossible, so that instead of dealing with the essence of the problem, irrelevant aspects are perceived and thought about. Problem-solving becomes slower for that reason. When new concepts are learned, the individual is not able to learn to screen out the specific irrelevant stimuli which are occasionally associated with the common elements which define the concept. Thus an overinclusive concept is learned. Indeed, as the condition becomes more severe, ideas distantly related to concepts learned in the past no longer seem to be screened out and these concepts become contaminated so that all thought becomes more vague and imprecise, and errors of reasoning increase. These individuals may well develop paranoid delusions as the result of this disorder. The only advantage this state offers is that on those occasions when normal people *mistakenly* screen out certain aspects as irrelevant to a problem (adaptive rigidity), and fail to solve it, overinclusive individuals at least obtain all the data. In fact overinclusive individuals are excessively flexible and original and occasionally this is an asset.

A completely different set of cognitive abnormalities can result from rote-learning defects. In old age and especially senile dementia, the capacity for rote learning becomes so poor that cognition is affected for this reason. The *facts* of new problems cannot be learned, and the problem cannot be solved for this reason. Any task involving the acquisition of new motor skills is affected (performance tests). Memory disorders tend to occur, not through a retention defect, but simply because new facts are never learned. For most people this only occurs with great age, so that it does not affect learning in earlier life. However, a lifelong minor handicap of this sort is produced by extreme extraversion. Extremely extraverted people are less able to learn, so that the more the cognitive task is dependent on facts which have been learned in the past, or the acquisition of new facts, the worse they tend to be. When the facts of the problem are few enough to be held in their memory span, they can solve problems accurately. When the data are too numerous however, they may have to resort to splitting up the

material and obtaining partial solutions, which they combine. They cannot learn the entire set of data so as to manipulate it simultaneously. This reduces their accuracy, although it increases their speed. Personality factors associated with extraversion also play their part. Such people tend to be less persistent and more impulsive, so that they tend not to check their thinking, tending to be fast but inaccurate. Extreme introversion produces the opposite effect. Here thought is slowed down by a tendency to check and be thorough, but accuracy is increased. Introverts also tend to display "adaptive rigidity" as they can quickly build up a set which may blind them to certain possibilities.

Physiological factors may play quite a different role. Anxiety and an excess of thyroid activity tend to increase the drive level of the individual, which for some reason speeds up the tempo of thought. This in itself is a considerable advantage, since it does not necessarily have any effect at all on accuracy. Unfortunately anxiety and introversion interact. When introverted people become too anxious, they tend to produce conditioned responses to the anxiety (fears, obsessional checking) which are so distracting that they slow down thinking much more than the higher drive speeds it up. Obsessional checking can, however, increase accuracy.

Since these main types of abnormality may be independent, various combinations of them are possible in individual cases. This could produce quite a complex pattern of disability. Individual differences in pre-illness level also complicate the picture.

This account is, of course, both speculative and incomplete. If more were known about the causes of error, no doubt other patterns of disability would be discovered. What is particularly lacking is any knowledge of the way *affective* disorders and cognitive abnormalities are related. There is every reason to believe that an affective illness can produce considerable cognitive impairment. Extreme excitability and distractibility obviously produce poor performance, and depressive thoughts no doubt are equally distracting. However depression may do more than this. Like some catatonic conditions it may produce an extreme slowing of mental processes which possibly has a basic physiological cause. However this, like many other problems must remain a mystery at present.

CHAPTER 7

Abnormalities of Motivation and “Ego-functions”

JAMES INGLIS

INTRODUCTION

ANY account of human abnormal psychology must attempt to deal with the so-called “higher processes” not only in relation to intellectual or cognitive functions but also in relation to affective or orectic functioning.

It seems to the present author that certain consistencies may be traced in at least three adjacent experimental areas of considerable importance to abnormal psychology, which are referable to the interaction of such higher processes with stress and the arousal of affect or motivation on the one hand, and with individual differences on the other.

Before these interrelationships can be described, however, some consideration must be given to the terms which will be involved in the description.

The notion of higher process is invoked simply to take into account the fact that the adult human being is capable of behaving in relation not only to changes in external, and in simple internal, stimulation, but also is capable of behaving in relation to an immense, and an immensely complex, range of self-produced stimulations or “symbols.”

Berlyne (1954) has discussed the usefulness of the notion of self-produced stimulation in, for example, relating experimental data concerned with “knowledge” within the framework of a stimulus-response psychology. He suggests that the way of talking about such self-stimulation, or “symbolizing,” formulated by Osgood (1952) provides at least a good beginning.

Osgood states that, “a pattern of stimulation which is not the object is a sign of the object if it evokes in an organism a mediating reaction, this (a) being some fractional part of the total behaviour elicited by the object and (b) producing distinctive self-stimulation that mediates responses which would not occur without the previous association of non-object and object patterns of stimulation.” (Osgood, 1952, p. 204.) Berlyne goes on to point out that, “Osgood’s scheme thus follows this pattern —

$$\boxed{S} \rightarrow r_m \dots \dots \dots s_{11} \rightarrow Rx$$

where S is the sign, r_m the mediating reaction (a part of the response pattern made to the signified object), and Rx is the overt behaviour evoked by r_m . It will be seen that r_m is the behavioural equivalent of the ‘concept’ or ‘meaning’ which a sign, in traditional accounts of symbolization, ‘conjures up’ in the interpreter’s ‘mind.’” (Berlyne, 1954, p. 297.)

It is not only “knowledge,” however, that can be conceived in these terms. Certain aspects of “emotional” or “orectic” behaviour can also be so conceived.

To put it at its simplest, when one “learns a word for X,” one does *not* simply learn to connect noises or marks on a piece of paper with their referent in a neutral sort of way. A wide range of symbols are primarily emotive by nature. Even those which are ordinarily neutral can, of course, acquire emotional overtones by appropriate manipulation.

The need for recognizing *both* cognitive *and* orectic aspects of symbolizing has been pointed out, for example, by Morris (1946). He has suggested that symbolic processes may exist, not necessarily exclusively, in several different “modes of signifying.”

Symbols in the “prescriptive” mode, for example, are of primary importance in human *cognitive* behaviour. These include symbols which are mainly concerned in arousing fractional anticipatory skeletal responses. The *orectic* aspect of behaviour is mainly the concern of symbols in the “appraisive” mode of signifying. In Osgood’s terms, if the r_m initiates mainly drive-producing or emotional responses, it is an “appraisor.”

In human abnormal psychology the appraisive content of symbolic processes (both verbal, pre-verbal and non-verbal) which are concerned with anxiety mediation are of very considerable importance. Such mediators, in the case of man, may not only be conditioned, “at the first level” so to speak, on simple tissue-injury-avoidance, as they may be with lower organisms. They may, in fact, be so remote from this

primary level as to appear as mediating many different "kinds of drive." Recently, however, Brown (1953) has suggested that there may, in fact, be a relation between anxiety drive and such higher-level motives as, for example, "self-esteem." He suggests that: "The important motivating component of many of the supposed acquired drives for specific goal objects is actually a learned tendency to be discontented or distressed or anxious in the absence of these goal-objects. On this view stimulus cues signifying a lack of affection, a lack of prestige, insufficient money, etc., would be said to acquire, through learning, the capacity to arouse an anxiety reaction having drive properties." (Brown, 1953, p. 12 *et seq.*)

This way of looking at human motivation is important on at least two counts. Firstly, it permits us to regard human motivational processes in the same light as the motivational processes of lower organisms. They may be different and more numerous in *kind*, especially in view of the vastly complex mediation systems used by man. We need not, however, regard them as being different in *source*, as is sometimes suggested by such expressions as "ego-involvement," and the like.

Secondly, it suggests that, in the consideration of individual differences, we may expect certain common elements to run through all aspects of, for example, "motivational intensity." In terms of personality structure some of the important individual differences may be, for example (i) neuroticism, which will determine the strength of the primary drives upon which anxiety may be secondarily conditioned and which will, in turn, then provide the basis for further learned drives; and (ii) introversion-extraversion, which, will determine the strength of the conditioning of the secondary, and other, drives.

The connexion between anxiety and socialization has been discussed by Mowrer (1950) while the importance of personality variables has been emphasized by Eysenck (1955). They have suggested that the process of socialization, i.e., the acquisition by the individual of a certain set of standards of conduct and behaviour may be considered to be mediated by a process of conditioning.

Now, if the process of socialization is based on a conditioning procedure, then the extreme introvert, subjected to a standard process of cultural indoctrination, should become over-socialized compared with the average sort of person. The extreme extravert, on the other hand, subjected to the same process, should become under-socialized compared with the average person. The contribution of neuroticism to this picture would be, perhaps, a basic "over excitability of the autonomic nervous system, particularly the sympathetic branch." (Eysenck, 1955, p. 53.) This would result, for the introvert, in an over-driven,

over-socialized individual; in other words in the tense, conflict-full dysthymic. The extravert would become over-driven and under-socialized; he would be typified, in fact, by the explosive hysterico-psycho-pathic individual.

It would follow from this argument that the appraiser elements related to "higher-level drives" in any individual's behaviour repertoire would be partly determined by his personality structure. In the introvert we would expect these to be strong and numerous, in the extravert, few and weak.

It is to be argued in this chapter that an important part of human orectic behaviour is related to the "handling" of such appraisive mediators, and that certain experimental data can be interpreted in terms of individual differences in dealing with such mediators under varying degrees of stress.

The principal consideration will be given to *that method of dealing with stress in which it may be said that individuals initiate avoidance reactions to their own anxiety-producing covert responses.*

It will become apparent that this formulation is akin to suggestions which have been put forward at various times, for example by Sears (1936), Angyal, (1941), and by Dollard and Miller (1950) and others, in an attempt to provide a behavioural interpretation of Freud's notion of "repression." Reviews of the evidence for such a formulation have been made by Sears (1943), Zeller (1950), and Farrell (1955).

There are, however, several important differences between previous adumbrations and the present chapter—

(i) In the first place, it is not the intention of the writer to review the evidence for, or against, "psychoanalytic theory" as such. It seems more worth-while to attempt to relate experimental data which have hitherto been more or less discrete rather than to recount attempts which have been made to evaluate virtually untestable "clinical hypotheses."

(ii) Secondly, previous authors have tended to discuss the elimination of anxiety-producing responses in terms of the more-or-less passive *inhibition* of such processes. The present writer wishes to emphasize rather the influence of active *avoidance* behaviour. It is to be suggested that the paradigm for the elimination of anxiety-producing mediating responses is to be found in experiments involving "escape-activity" rather than in experiments dealing with the simple exclusion of unrewarded responses.

Thus, in an animal like the rat, whose mediators are (comparatively speaking) few, anxiety-producing stimuli are mainly located, so to speak, externally. Hence they may be dealt with by straightforward, overt avoidance behaviour.

In man, however, both the anxiety-producing stimuli and the behaviour initiated for the reduction of anxiety may be much less overt, and may, in fact, consist in the suppression or avoidance of certain symbolic activities.

(iii) Thirdly, it must be taken into consideration that such avoidance-activity may have a more or less beneficial influence on the organism's repertoire of responses. Commonly symbols may fulfil both

FIG. 7.1

“appraisive” (emotional) and “prescriptive” (cognitive) functions. By initiating *too much* avoidance, therefore, the individual may deprive himself of certain problem-solving “tools” and so may reduce the efficiency of his adjustment. On the other hand, insufficient avoidance may be equally maladaptive, since the consequent increase in the emotive properties of a situation may also be disruptive of efficient behaviour. Somewhat similar points have been made by Cameron (1947).

(iv) This latter view, that certain avoidance behaviour can be practised too little or too much leads to a fourth important consideration which has, in general, been ignored by previous writers. This relates to the interaction to be expected between *situations of differential stress* and *differential individual susceptibility to stress*.

It has emerged from several studies (cf. chapters by Jones in this HANDBOOK) that adequacy of performance may not be a simple linear function of drive-strength. There may, in fact, be an *optimum* level of drive for the execution of any task, and, in general, the more complex the task the lower the optimum drive level required for its efficient execution. The general form

of the relationship between drive and efficiency is curvilinear, taking the form of an inverted U-curve. (Cf. also Hebb, 1955 and Duffy, 1957.)

The avoidance of anxiety-mediating self-stimulation may be regarded as a kind of problem-solving task. It may be argued, therefore, that stress and the personality variables related to susceptibility to stress have a similar effect upon the achievement of an adequate “solution” involving the *avoidance* of anxiety-mediators, as they may have upon the efficient positive execution of other behaviours.

This notion agrees with the conclusion reached by Iverson and Reuder (1956) in their review of studies of “ego-involvement.” They say: “Generalizing from their review, the writers propose the hypothesis that varying reactions to ego-involving conditions reflect, at least in part, a continuum of motivation. The relationship between degree of ego-involvement and efficacy of response appears to be a curvilinear one, inhibitive or disruptive at the extremes and optimally facilitative near the middle. There also appears to be a common personality dimension which is responsive to ego-involving conditions.” (Iverson and Reuder, 1956, p. 175.)

In view of the working hypothesis adopted here it is suggested that their “continuum of motivation” may be regarded as one of differential “social stress” or “socialized-anxiety-production,” and in terms of the propositions which have been put forward concerning the likely relevance of personality structure, their “common personality dimension,” may be regarded as falling along a composite continuum comprising, in turn, neurotic extraverts (NE), stable extraverts (SE), stable introverts (SI), and neurotic introverts (NI).

The relations discussed may be conceived as illustrated in Fig. 7.1.

Thus, in situations of low objective “external” stress, individuals at the NI end of the composite continuum NE-NI may have already begun to initiate the avoidance of anxiety-mediators, since the motivational content of such reactions may, even at this stage, be sufficiently high for these individuals to be functioning “maximally” in respect of this avoidance activity. Such a process, under these circumstances of low objective stress may, however, be otherwise maladaptive since, as has been pointed out, it may concomitantly reduce access to other important cognitive aspects of these same mediators. Under the same circumstances of stress the individuals at the NE end of the continuum may not yet have begun to initiate avoidance behaviour.

On the other hand, in circumstances of high objective stress, the individuals at the NE end of the continuum will now initiate powerful avoidance behaviour. Individuals at the NI end, however, are now being

subjected to so much stress that successful avoidance activity may be disrupted.

In such a situation both the powerful avoidance activity and the inability to avoid may be maladaptive, since the first leads to the diminished availability of possibly relevant cues and the second leads to the increase of anxiety in an already stressful situation.

It is suggested that this scheme may be used to

relate data from three adjacent experimental areas, namely—

1. Studies concerned with "Perceptual Defence."
2. Studies concerned with the "Zeigarnik Effect" and
3. Studies of "Level of Aspiration" phenomena, which may now be considered in that order.

STUDIES IN "PERCEPTUAL DEFENCE"

Description of the Phenomena¹

In 1947 Bruner and Postman used the notion of "perceptual defence," and its obverse, "perceptual sensitization" or "vigilance," to relate together results which they had obtained in an experiment designed to examine the connexion between associative reaction-times and recognition thresholds. In this study the association times of nineteen undergraduates were measured to ninety-nine words, some of these words being "neutral" in connotation (e.g., *clock*, *book*, etc.) and some "emotional" (e.g., *penis*, *hymen*, etc.). For each subject there were then selected the six words giving the longest, the six giving the median, and the six words giving the shortest reaction-time. A fortnight later the tachistoscopic exposure time necessary for each subject's recognition of the chosen words was examined. A correlation ratio was run for each subject and in seventeen out of the nineteen cases, a significant curvilinear relationship was shown to exist between the two measures. A generalized z-score function was plotted for the group (Fig. 7.2), the *eta* being 0.124 with a standard error of 0.054.

It can be seen from this figure that the relationships between association time and recognition time generate an inverted U-shaped distribution. The authors suggest that this is because, for most of their subjects, time of recognition increases as reaction-time; since, with the increase in emotionality of the stimulus, recognition is avoided as long as possible, as an anxiety-reducing technique, this constituting perceptual defence. Other subjects, however, tended to recognize more quickly words to which they had initially returned long reaction-times; they, in fact, showed perceptual vigilance or sensitization.

¹ This section will be concerned only with the results of experiments in perceptual defence in the visual modality. Those interested in similar work in the auditory modality are referred to further studies (by Cogan, 1956; Davids, 1955; Kleinman, 1957; Kurland, 1954; Lazarus, Eriksen and Fonda, 1951; Mason and Garrison, 1951; and Vanderplas and Blake, 1949). Studies of the effects of "positive values" (Allport, Vernon and Lindzey, 1951) on perception will not be examined although there are, of course, relations between these and the studies on "negative values" reviewed here (see Klein, Schlesinger and Meister, 1951; Postman, Bruner and McGinnies, 1948; Solomon and Howes, 1951; and Postman, 1953b).

A further demonstration of the defence phenomenon was then reported by McGinnies (1949). He presented sixteen student subjects with seven emotional and eleven neutral words and established their recognition thresholds for these words tachisto-

FIG. 7.2. AVERAGE RECOGNITION TIMES FOR WORDS ELICITING VARYING ASSOCIATIVE REACTION-TIMES
(From Bruner and Postman, 1947)

scopically. He also took readings of the subjects' galvanic skin responses. The subjects reacted with G.S.R.s of significantly greater magnitude during the pre-recognition presentation of the emotional words than they did during the pre-recognition presentation of the neutral words (see Fig. 7.3).

They also required longer exposures for the accurate recognition and report of the emotional words (see Fig. 7.4).

McGinnies concludes that: "The findings are interpreted as representing conditioned avoidance of verbal symbols having unpleasant meanings to the observer. The stimulus word serves as a cue to deeply embedded anxiety which is revealed in autonomic activity as measured by the G.S.R. Avoidance of further anxiety is contemporaneously aroused in

FIG. 7.3 GROUP AVERAGES OF GALVANIC SKIN RESPONSE TO NEUTRAL AND CRITICAL WORDS DURING PRE-RECOGNITION EXPOSURES

(From McGinnies, 1949)

FIG. 7.4. MEAN THRESHOLDS OF RECOGNITION OF THE OBSERVERS TO THE NEUTRAL AND EMOTIONALLY-CHARGED WORDS

(From McGinnies, 1949)

the form of perceptual defence against recognition of the stimulus object." (McGinnies, 1949, p. 251.)

Criticisms and Controversies

The notions of perceptual defence and vigilance have come in for a good deal of criticism, on several grounds. The main forms of criticism may be grouped, for convenience, under several heads and separately considered as follows—

LOGICAL DIFFICULTIES

One difficulty which has been seen to lie in the notion of perceptual defence comes from the apparent paradox that, in order to know what to avoid, the subject must first recognize the stimulus which is to be avoided. This difficulty has been recognized from the

beginning and was dealt with by Bruner and Postman in the following terms—

The paradox remains only so long as we (1) restrict the definition of *recognition* to one type of response—veridical report and (2) insist that all systematic responses to the stimulus depend on the *prior* occurrence of correct recognition. Neither of these restrictive assumptions is necessary. There can be tripped off, by the presentation of a stimulus, a multiplicity of response tendencies among which veridical reporting is only one, albeit a most important one. Other systematic reaction tendencies tripped off by the stimulus may be largely affective in nature and lead to various forms of avoidance responses. Each of these possible responses has its own threshold, determined by characteristics of the stimulus end and by the directive state of the organism (differential "availability" of the responses). Thus, veridical report has *its* threshold, and affective avoidance response has

its. As our experiments suggest, the threshold for affective avoidance response is frequently lower than the threshold for veridical report. . . . If this rather reasonable assumption of the hierarchy of thresholds be accepted, a Judas eye notion of double-perception is not required to account for the phenomena of "defensive" perception in which avoidance responses seem to precede correct recognition. (Bruner and Postman, 1949, p. 26.)

Despite this proposal, which derives plausibility from work on "subception" (McLeary and Lazarus, 1949; Lazarus and McLeary, 1951) as well as the study by McGinnies already cited, the same type of difficulty has been raised by others including Howes (1952) and also by Allport (1955).

The former author has, however, been answered by Postman (1953a) and Allport has himself noted that—

The term perceptual defence is misleading in that it suggests that defence is accomplished *through* perception (i.e. through the abortive character or self-retardation of the perceptual process) an interpretation that raises the dilemma of a subconscious, preperceiving perceiver. If we could consider that some fractional stimulus element in the situation, rather than the complete and meaningful stimulus pattern, can, in short exposures, lead the subject *to avoid perceiving anything further with respect to that stimulus pattern* until long exposures give him no escape from perceiving it, the matter could be more simply explained. It would not be a case of "perceptual defence," in the sense of raising the threshold, but simply of an inhibition of perceiving that has been conditioned to certain (actually perceived) cues. (Allport, 1955, p. 333.)

Studies by Bricker and Chapanis (1953) and by Murdock (1954) have provided evidence that, in fact, identification of words at near-threshold values is *not* necessarily an all-or-none matter so that it is not inconceivable that some such process as Allport suggests may, in fact, take place.

WORD FREQUENCY

A much more telling kind of criticism which has been levelled against the notion of perceptual defence is involved in the suggestion that the relative frequency of usage of words, as determined for example by the Thorndike-Lorge word-count (1944) is a more important determinant of recognition threshold than is the relative "emotionality-neutrality" of the words used in the experiments cited.

The principal proponents of the word-frequency criticism have been Howes and Solomon (1950). These authors examined the problem experimentally (1951) and were able to show that the visual recognition threshold of a word, as measured tachistoscopically, is an approximately linear function of the logarithm of the relative frequency with which the word appears in a word-count, the product-moment

correlations between the two variables ranging from -0.68 to -0.75 .

An even more convincing study has been reported by Solomon and Postman (1952) which also examined the relationship between frequency of prior usage and recognition threshold. This latter study represented an advance on the Howes and Solomon experiments since it did not rely merely on an actuarial control of word-frequency. The undergraduate subjects in this experiment were required to read and pronounce different nonsense (actually Turkish) words. The number of times they were required to read the words ranged from once to twenty-five times. The subjects' recognition thresholds for these words were then compared with other words which they had *not* read before and it was found that thresholds varied inversely with frequency of prior usage. A similar experiment with equivalent results has been reported by King-Ellison and Jenkins (1954).

Goodstein (1954) has also reported the further analysis of a set of results obtained by Aronfreed, Messick and Diggory (1953). These authors had, in their study, confirmed that the mean visual recognition threshold for unpleasant words was significantly higher than the mean threshold for neutral and pleasant words. Goodstein was able to show that there was a parallel difference in frequency between the categories of words used.

Bresson (1955) in his brief review, also finds reasons for emphasizing the importance of frequency. His conclusion seems too facile, however, since he gives little or no consideration to those studies which provide evidence for the importance of other factors. In fact it has been recognized from the beginning that relative frequency might be an important determinant in the recognition situation. Bruner and Postman, for example, stated that—

We do not believe, of course, that perceptual defence is the only factor responsible for the impairment in recognition associated with increased reaction time. Part of the correlation, particularly in the case of very fast reaction words, can be ascribed to familiarity. The positive correlation between popularity and speed of associative responses is a well established empirical fact (Marbe's Law). A familiar stimulus will not only elicit a quick and popular response, but it is also likely to be recognized readily, since familiarity will facilitate "closure" when only part of the stimulus word is seen under rapid exposure. *Some* of our fast reaction-fast recognition words are indeed among those which are known to give quick, popular responses. Familiarity, cannot, however, account in entirety for the correlation between speed of association and speed of recognition. Many words with relatively *fast* recognition and reaction times are not among those which normally yield quick, popular responses. And, conversely, among the *slow* and *medium* recognition and reaction words are many which, according to the conventional norms, should have evoked

quick and popular responses. These discrepancies we attribute to the differential effect of perceptual defence in the face of emotionally charged stimuli. (Bruner and Postman, 1947, p. 75.)

Replies have been made, by other supporters of the notion of perceptual defence, to the charge that word frequency can account, by itself, for the phenomena observed in their experiments. McGinnies (1950), for example, attempted to rebut Howes and Solomon's

FIG. 7.5. CURVES OF RECOGNITION TIME CONSIDERED AS A FUNCTION OF ASSOCIATION TIME
(From Delucia and Stagner, 1953)

arguments on two grounds. In the first place he suggested that their assumptions, based on actuarial methods, of the frequency of usage of the emotional words were too low, and, secondly, he suggested that the correlations which Howes and Solomon (1951) reported between frequency and threshold were spurious since these authors drew a regression line through the two distributions represented by the emotional and neutral words, whereas such lines drawn *within* each distribution show no such marked relationship. The study by Solomon and Postman (1952), noted above, appears to answer both these counter-arguments of McGinnies since they obtained results consistent with the importance of word frequency *without* employing the word-count technique and using a *continuous* range of word frequency.

Cowen and Beier (1954) however, report an experiment with fifty-nine students who were required to decipher progressively less blurred carbon copies of words, some emotional, and some neutral. They found that significantly more trials were required to achieve the correct report of the former as compared with the latter. They also found *no* significant correlation between threshold and frequency ($r = +0.003$).

Lazarus (1954) has pointed out that, after all, the two factors of familiarity and emotionality may interact; frequency itself may be partly a function of an individual's needs as well as experience.

A study has been reported by Delucia and Stagner (1953) who tested twenty members of the National Guard in an association time, and in a recognition threshold, situation in a way analogous to the method of the original study by Bruner and Postman (1947). Delucia and Stagner provide a graph (Fig. 7.5) of their results which show interesting similarities to the one given by Bruner and Postman (see p. 265, Fig. 7.2).

Delucia and Stagner point out that: "Both show an initial negative acceleration, a peak and a decline. The final segments of the two curves differ, perhaps because we have ten steps on the x-axis whereas Bruner and Postman have only five. The overall resemblance, however, seems noteworthy." (Delucia and Stagner, 1953, p. 302.) It should be noted that *even with frequency held constant*, these authors report that recognition time is still significantly related to association time and they conclude that: "Our data seem to support both the Bruner and Postman emphasis on emotional factors, and the Solomon-Howes stress on frequency." (Op. cit., p. 306.)

An ingenious experiment by Wiener (1955) used the *same* words as both threat and neutral stimuli by placing them in different contexts—for example, placing the word *fairy* in a context which emphasized its homosexual connotation and in a context which stressed its supernatural connotation. Differences in threshold were shown; in this case, however, the critical words were perceived *more quickly* when they had been in a threat context than when they had been in a neutral context.

From this review of criticisms and rebuttals it can be concluded that in any well-conducted experiment designed to elucidate further the phenomena of perceptual defence it is certain that there must be taken into account the important factor of word frequency, and also, in view of the findings of McGinnies, Comer and Lacey (1952) word-length should be controlled as well.

It is probably the case, however, that word frequency, by itself, cannot account for all the phenomena reported and that the notion of perceptual defence cannot be explained away in terms of this factor alone.

RESPONSE SUPPRESSION

Another kind of criticism which has been made of the apparent defensive phenomena is that they may, in fact, be due, at least in part, to the deliberate withholding of responses to emotional words by the subjects until it is abundantly clear what words are being shown, simply because of the embarrassment involved in reporting words like *penis*, *whore*, and the like, in an experimental situation.

This type of criticism has been put forward by Howes and Solomon (1950) who, it will be recalled,

are also among the main proponents of the word-frequency argument.

Whittaker, Gilchrist and Fischer (1952) have published a note on data which they claim support the idea of "response suppression." When words derogatory to negroes were projected and the situation was conducted by a negro experimenter, these authors claim that the negro subjects' protocols showed evidence of "conscious suppression." Their case is somewhat weakened, however, by the fact that although this suppression effect was only noted with this $S \times E$ combination there was *no* significant difference between the mean illuminance threshold value for such words for this group of subjects and two other (white) groups also taken by a negro experimenter.

Postman, Bronson and Gropper (1953) report a more convincing study which was designed experimentally to vary the likelihood of response suppression. The subjects were ninety-six students; word frequency was controlled by the word-count method and thresholds were established by different levels of illuminance. Four different sets of instructions were used. Thus, one group was "uninformed," in that they were not warned to expect "taboo" words. A second group was "informed," i.e., they were told what to expect. A third group was "facilitated"; they were given instructions designed to discourage the withholding of taboo responses. A fourth group was "inhibited," being given instructions designed to encourage the withholding of responses. The results of this experiment showed that the thresholds for the taboo words were significantly *lower* than the thresholds for the neutral words. The relative thresholds for neutral and emotional words, however, varied significantly with the nature of the instructions, as would have been predicted from the response-suppression hypothesis.

The response-suppression hypothesis has also been favoured by Bitterman and Kniffen (1953). They used a tachistoscopic procedure with forty female students and they derive support for their hypothesis mainly on the basis of the fact that there was a significant decline in threshold for taboo words as a function of order of presentation (see Fig. 7.6).

These authors note that: "The fact that no order-effect is evident for the neutral words suggests that the order effect for the taboo words cannot be attributed to tachistoscopic practice. It must represent, instead, the development of insight into the essential nature of the situation. In the words of one subject, 'I caught on to what you were doing and then expected anything.' This result is precisely what might be anticipated on the assumption that differences in the threshold of taboo and neutral words (beyond those attributable to frequency of experience) may be

accounted for in terms of differential readiness to report rather than in terms of perceptual functioning." (Bitterman and Kniffen, 1953, p. 250.) It should be noted from Fig. 7.6 however, that the difference between taboo and neutral words was in fact significant even in the final position, a fact for which the authors' hypothesis does not seem to account.

FIG. 7.6. MEAN THRESHOLDS (IN HUNDRETHS OF A SECOND) FOR TABOO AND NEUTRAL WORDS AS A FUNCTION OF ORDER OF PRESENTATION

(From Bitterman and Kniffen, 1953)

Lysak (1954) also favours the response-suppression hypothesis, although it does not seem to the present writer that his investigation of the effect of shock on thresholds provides crucial evidence on this point.

In other studies in which the subjects were given instructions which led them to expect taboo words, Lacy, Lewinger and Adamson (1953) and Freeman (1954, 1955) have shown that this may, in fact, lead to *lower* recognition thresholds for the taboo than for the neutral words, a fact which will be discussed in more detail later (see pages 272 and 273).

In the meantime some of the data which have been produced by the supporters of perceptual defence in reply to the suggestion that their findings are explicable in terms of response suppression may be considered.

McGinnies and Sherman (1952) examined, tachistoscopically, the recognition thresholds of twenty male undergraduates for eight five-letter words of approximately equal frequency and of neutral meaning. Half of these task words were presented to the subjects

immediately after the full exposure of a taboo word, half were presented following the exposure of a neutral word. These authors were able to show that the subjects' thresholds for the former were significantly higher than for the latter. They interpreted their findings in terms of the *generalization of an avoidance reaction* from the taboo to the neutral words. They argue that there can be no reason to suppose that subjects voluntarily withheld responses to stimuli which were, in fact, themselves neutral in connotation.

Cowen and Beier (1950) and Beier and Cowen (1953) have also shown that even when subjects are alerted to the fact that threat words are about to be exposed, they may still require a greater number of trials and more time for the correct report of threat words than for neutral words. These authors in one study (Cowen and Beier, 1954) checked on the possibility of response suppression in several ways: by warning the subjects what words they were to expect, by cross-examining them after the experiment, by estimating differences between male and female subjects and by comparing the effect on male and female subjects of like-sex and different-sex experimenters. The results obtained were, in the authors' view, more consistent with the perceptual defence hypothesis than with the notion of response suppression.

Newton (1955) has also examined tachistoscopically visual recognition thresholds for pleasant versus unpleasant words equated for word-count frequency. He found significantly fewer errors for the pleasant words. Response suppression would not seem to be an adequate explanation here since the unpleasant words (e.g., *shame*, *cruel*, etc.) were not such as to make it likely that the subjects would withhold verbal report simply from embarrassment.

It may be concluded, therefore, that the effect of response suppression, like the effect of word-frequency, must certainly be taken into account in any well-designed experiment concerned with perceptual defence. It seems, however, that when the possibility of withholding responses has been, as far as possible, eliminated or controlled, differences in threshold and/or in response time remain, and so remain to be explained.

PERSONALIZED ANXIETY

Another general type of criticism has been made of some of the material employed in some perceptual defence experiments. Chodorkoff (1955) has pointed out that the use, for example, of taboo words does not guarantee their personal, anxiety-arousing relevance for every subject and that any adequate experiment must ensure the employment of such personally relevant threatening and neutral stimuli.

A search of the literature suggests that at least two

main methods have been employed in attempts to secure items so that they contain a certain amount of personalized anxiety. In the first place, words have been employed which have elicited "complex-indicator" responses (e.g., delayed reaction-times) in word-association situations. Secondly, stimuli have been employed to which some anxiety-reaction has been experimentally secured (e.g., by association with electric shock). A brief review may be made of such studies under the separate heads.

1. Word Association

It will be recalled that this is the method initially used by Bruner and Postman (1947) to secure their "defended against" stimuli.

The same technique has been employed by Eriksen (1951) and by Chodorkoff (1954) who both obtained results consistent with the hypothesis of perceptual defence, and by Delucia and Stagner (1953) in the study already described (page 268).

A good recent study has been reported by Singer (1956) who also used the word association method.

FIG. 7.7. DIFFERENCE BETWEEN MEAN THRESHOLD VALUES FOR EMOTIONAL AND NEUTRAL WORDS OF INDIVIDUAL SUBJECTS ON BOTH TESTS

(From Singer, 1956)

He estimated illuminance threshold for twelve young women on two occasions to two lists of eight neutral and eight emotional words respectively. He notes that: "From each of the two tachistoscopic tests, two mean recognition thresholds were obtained for each subject; the mean recognition threshold for the eight emotional words shown (E_1 and E_2) and the mean recognition threshold for the eight neutral words shown (N_1 and N_2). The differences $E_1 - N_1$ (in the case of the first test) and $E_2 - N_2$ (in the case of the second test), indicate the amount by which the mean recognition threshold for emotional words exceeds the mean recognition threshold value for neutral words. A positive value for this difference would indicate that the mean recognition threshold for emotional words was greater than the mean recognition threshold for neutral words. A negative value

for this difference would indicate the reverse." (Singer, 1956, p. 307.) It can be seen from Fig. 7.7 that six subjects showed defensive reactions to the emotional words, while two showed vigilance reactions, and that most of the subjects showed consistency of reaction over the two occasions. Overall the defence effect was significant.

Mednick, Harwood and Wertheim (1957) secured five neutral and five disturbing words, controlled for frequency, for twenty-four students on the basis of word-association test responses. When it was suggested to the subjects that an apparently moving (but actually motionless) point of light in a dark room would trace out sentences containing the selected words, *fewer* of the disturbing words were reported, and when they were they showed a greater latency than did the neutral words.

It is interesting to note that all these studies took careful consideration of word frequency factors and, by ensuring the relevance of the stimuli, obtained results consistent with the perceptual defence hypothesis.

However, as Singer has cautiously put it: "In this experiment, and in several others, the objective criterion of the emotional connotation of a word has been the duration of reaction-time. Strictly speaking, the present experiment has only shown that higher thresholds (and the reverse) are obtained for words of a long reaction-time: that the words were actually emotional has not been unequivocally demonstrated. Our present knowledge indicates that two determinants are mainly responsible for the duration of reaction-time: the associative strength of the stimulus word and its emotional effect on the subject." (Singer, 1956, p. 308.)

2. Association with Shock

An experiment into the phenomena of "subception" (or "discrimination without awareness") by Lazarus and McCleary (1951) incidentally provided information of use in the examination of the problems of perceptual defence. In this study ten paralogues were presented to the subjects, and five of these were paired with an electric shock so that a conditioned P.G.R.s was obtained. When the ten paralogues were now exposed at speeds too rapid for the subjects accurately to report which stimulus was being presented, it could be shown that the syllables which had been previously paired with shock gave greater P.G.R.s than did the neutral syllables. It should be noted, however, that there was in this case *no* difference overall for the accuracy of report between shock and non-shock syllables.

An experiment by Reece (1954) used a factorial design to examine the effects of escapability and predictability of shock on the recognition thresholds

and learning of nonsense syllables by seventy undergraduate subjects. He was able to show that when he expressed his results as ratios between post- and pre-learning (i.e., shock-association) thresholds then there was a significant difference between these threshold ratios for the non-escape shock group compared with the escape shock group and also compared with the shock group.

Similar results have been reported by Rosen (1954) who argued that if the perception of a stimulus is painful to the organism and it cannot do anything directly to avoid it, then one consequence may be the raising of the recognition threshold for such a stimulus. This author was able to show, in accordance with prediction, that non-avoidable shock did raise the tachistoscopic recognition threshold of shock-associated words. The role of the learning process in the use of either defence or vigilance as the preferred mode of response to shock-associated stimuli has also recently been studied by Dulany (1957).

3. Other Methods of Securing Relevant Stimuli

Various other methods have been employed in order to secure personalized anxiety. For example, a study by Eriksen (1950) showed consistency between the handling of T.A.T. themes (as regards aggression, etc.) and the perceptual recognition of such relevant "theme" words. Those subjects who, for example, blocked or showed other emotional indicators in their stories as regards aggression also had higher tachistoscopic visual thresholds than those who did not.

Neel (1954) used groups chosen for being prone to conflict over sex or aggression and compared their recognition threshold for pictures containing mild or direct sexual or aggressive content with the corresponding thresholds of a "no-conflict" control group. Her results suggest that there may be differences in the kind of response made to different *kinds* of anxiety-provoking stimuli.

An interesting application of the notion of personalized anxiety applied to a single case has been reported by Walton (1954). Applying the method originally used by Rosenstock (1951) he was able to show that sentences containing material judged to be stressful on the basis of a patient's case-history were more defended against in terms of illuminance threshold than were similarly selected neutral items. Walton (1957) has also followed up these results on groups of patients.

A study by Carpenter, Wiener and Carpenter (1956) has shown that when anxiety-provoking words are individually chosen (from results on a "sentence completion" type of task) for subjects on the basis of their susceptibility to conflict in a particular area

(e.g., sex, hostility, etc.) then the defence or vigilance behaviour in the perceptual situation is consistent with the behaviour in the sentence completion situation.

Smith (1953) however, failed to show differences in the recognition of hostile and neutral words in subjects rated as hostile or non-hostile on the basis of M.M.P.I. scores and a "hostility scale."

for emotional words may be *lower* than for neutral words.

In an article by Lacy, Lewinger and Adamson (1953) an experiment is reported (and its replication) in which thirty undergraduate subjects were tachistoscopically presented with neutral and obscene taboo words under three different conditions; i.e., (1) no knowledge; (2) general knowledge (in which each

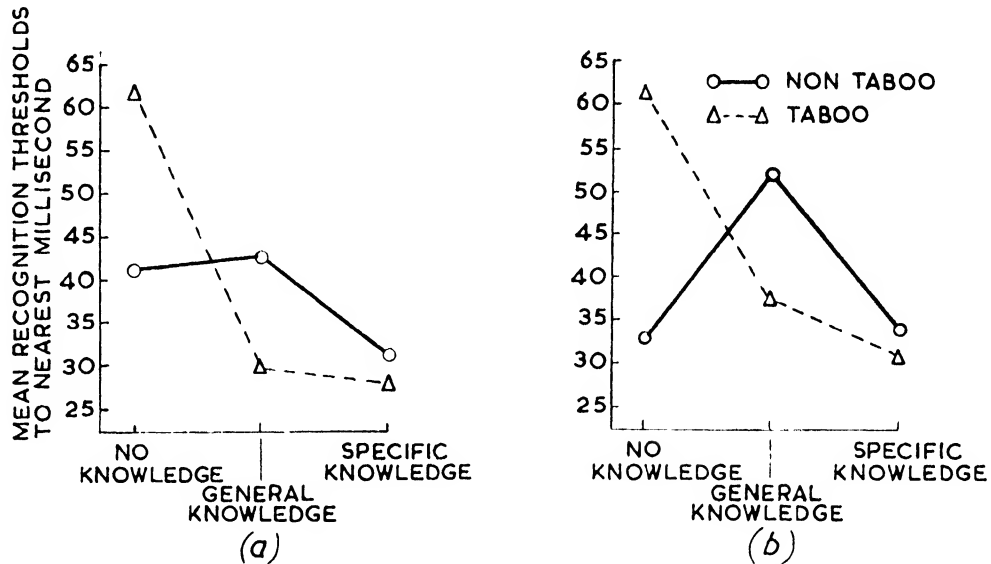

FIG. 7.8. (a) THE RECOGNITION THRESHOLDS FOR THIRTY SUBJECTS IN EXPERIMENT I TO THE FIRST WORD SEEN. (b) THE RECOGNITION THRESHOLDS FOR THIRTY SUBJECTS IN EXPERIMENT II TO THE FIRST WORD SEEN

(From Lacy, Lewinger and Adamson, 1953)

Spielberger (1956) reports on differences in oral and written recognition for stuttered words by stutterers and a control group of non-stutterers. There were differences in oral, but not in written, recognition thresholds. The author interprets his results as favouring the response-suppression hypothesis. This experiment is based on the assumption that stuttered words are emotionally loaded for stutterers. It should be noted, however, that recent work by Cherry and Sayers (1956) suggests that factors other than orectic may be of prime importance in stuttering behaviour.

Having discussed some of the main areas of controversy which are to be found in the work on perceptual defence, we may now turn back a little to examine some apparent contradictions which have arisen and which have appeared principally in studies concerned to elucidate the possible role of response suppression. It will be recalled that certain studies which permitted the subjects to *expect* the presentation of emotional or taboo words actually demonstrated that, under such conditions, the recognition thresholds

subject was told what *kind* of words to expect); and (3) specific knowledge (in which each subject was told exactly what words were to be shown). The found recognition thresholds for the two kinds of words are best described graphically (see Fig. 7.8).

The differences between conditions of knowledge were shown to be significant and the interaction Taboo \times Knowledge was also significant. The small apparent differences between the experimental and replication results were not significant. The authors note in their discussion of these results—

The present experiment grew out of work which initially has been theoretically explained by the notion of perceptual defence. Competing with this conception is the explanation offered by Howes and Solomon which supposed that the slower times for the taboo words is due to the lesser frequency with which such words appear in visual experience. The present experiment enlarges the evidence with which these competing theories must deal. It is now necessary, not only to account for the longer reactions for taboo words seen under McGinnies'

conditions, but also for the shorter reaction times seen under our "warning" conditions. In addition the competing theories must deal with the fact that differences in recognition thresholds involving taboo and non-taboo words disappear with habituation in experiments of this sort. The Howes-Solomon theory can account for the slowness with which taboo words are seen without warning, but it cannot explain the fact that such words are seen more quickly than non-taboo words when expectation exists. Further, the Howes-Solomon theory offers no grounds for explaining the habituation effects described above.

Looked at in the context of McGinnies' original theory the results suggest very strongly the bipolar character of the personal conditions which affect the speed with which perceptions are reported. In a sense, the experiment is a test of Bruner and Postman's views that these personal conditions are of such a nature that at some times they operate to defend against stimuli and at others to promote alertness to the reception of stimuli, whether defensiveness or alertness occurs depending upon the need prevailing in the receiver. (Lacy, Lewinger and Adamson, 1953, p. 173.)

These authors conclude that such differences with differing instructions are explicable in terms of changing dominance of "set."

Substantially the same results for forewarned subjects are reported by Freeman (1954). This latter author has also reported a study (Freeman, 1955) again using tachistoscopic recognition of taboo and neutral words by students. In one experiment, forewarning was used as one of the variables, and, in another, ego-involvement was employed. That is to say, the subjects were warned that the perceptual task they were about to do was related to academic success and aptitude. The effect of this forewarning was, as before, to reverse the speed of differential perception of taboo words. The effect of ego-involvement, on the other hand, was to speed up perception generally but to leave the neutral words as the faster perceived.

In fact, these findings illustrate what had been evident from Bruner and Postman's (1947) original study, that any notions designed to describe and explain the phenomena which exemplify perceptual defence must also make room for the obverse phenomena of perceptual vigilance.

Perceptual Defence and the Mediation-Motivation Hypothesis

The role of mediation-like processes in perception has been emphasized, from the "neuropsychological" point of view, by Hebb (1949) whose main concern has been to propose a model for perceptual processes which involves elements which are to some extent the neurological analogues of "mediators." Hebb adduces evidence mainly from the work of Senden (1932) and Riesen (1947) to show that apparently "simple"

perceptions are in fact complex; that they depend to a considerable extent on the self-stimulation provided, for example, by oculo-motor activity, and that their apparent simplicity and immediacy is only the end result of a long learning process.

Vernon (1955) has discussed the role of *schemata* in perception. Berlyne (1951), from the Hullian point of view, has made proposals suggesting that "perception" should, in behaviour theory, be introduced as an intervening variable, and be allotted the status of a stimulus-producing response.

Now the availability, to the organism, of such stimulus-producing responses in perceptual behaviour may be a function of several factors and among these the two most important are likely to be "habit strength" (e.g., as determined by word frequency) and "drive status"¹ (e.g., in terms of their role as, say, "anxiety mediators"), the latter quality depending not only on stimulus quality but upon susceptibility factors within the individual. (This is in agreement with the point made by Klein and Schlesinger (1949), by Lazarus (1955) and by Eriksen (1954b) among others, that one of the antecedent conditions which must be taken into account in such experiments is the "kind of individual" used as subject.)

Let us now consider what seems to happen in the situations of high and low stress such as were postulated at the beginning of this chapter.

1. *Low stress:* In a perceptual situation in which the habit strength of the mediators involved is held constant at approximately asymptotic value and the drive value of such mediators approaches a minimum, then individuals at the *NE* end of the suggested personality continuum may not be concerned to initiate any avoidance behaviour towards such mediators. Individuals at the *NI* end of the continuum, however, being much more susceptible to stress, may have already begun to initiate such avoidance (i.e., anxiety-reducing) activity. In terms of performance, then, individuals *NE* may appear to show perceptual vigilance whereas individuals *NI* are at this time showing evidence of perceptual defence.

2. *High stress:* In situations of similarly constant habit strength, but where the drive value is high, then, as in simple learning, the second part of the Yerkes-Dodson law effect becomes evident. Individuals *NE* now perform more markedly their mediation-avoidance activity; whereas, by reason of the fact that their drive component has now become excessive, individuals *NI* are now avoiding less adequately so that, in terms of performance, the vigilance and defence roles are now reversed.

¹ The effect of such determinants on perceptual behaviour has been examined experimentally by, for example, Engler and Freeman (1956), by Rockett (1956), by Newton (1956), and by Rigby and Rigby (1956).

These processes can be illustrated by their application to an earlier diagram (Fig. 7.9).

The advantages of this model seem to be as follows—

1. It permits the dismissal of "agency" notions (see Howie, 1952) since mediation may be triggered off, and presumably, therefore, *not* triggered off, by responses below the threshold of verbal report (Bugelski, 1956).

2. It takes into account both the components of word frequency and emotional value.

FIG. 7.9

3. It reduces the apparent gulf between response suppression and perceptual defence since the explanation may now be couched in terms of different levels of readiness to report. Thus, at one level we have the avoidance of the production of overt mediators towards other organisms and, at another, the avoidance of the production of covert mediators toward the organism itself.

4. It takes into account the apparently paradoxical phenomena of vigilance and defence and deals with such curvilinear relationships as were first noted by Bruner and Postman (1947).

It can also deal with the apparent vigilance effects which have been noted when the subjects have been warned to expect taboo words (as in the study of Lacy, Lewinger and Adamson, 1953) by suggesting that the effect of such instructions is to reduce anxiety, so producing indifference to avoidance.

5. Most important of all, this model explicitly states the parameters of individual differences which are expected to be relevant to performance in the perceptual defence situation.

Certain other studies which have been carried out in the investigation of perceptual defence phenomena

may now be reviewed in order to see if they can be resolved with the model proposed.

Consideration of Some Further Evidence

It is evident that an ideal experiment, specifically designed to test the hypothesis put forward would, at least—

(a) control for such factors as word frequency and the likelihood of response suppression, and

(b) vary systematically such factors as personality structure and the anxiety arousing relevance of the stimuli used, and also take account of their interaction.

In default of such a single experiment the results of a number of further studies from the literature may be recounted which have commonly taken a few of these considerations into account.

It should be pointed out that, in the ordinary visual-threshold experiment it is likely that situations of low stress will be principally involved. That is to say, we shall be dealing mainly with the left-hand side of the postulated inverted U-distribution, and it will follow that these will mainly show a relationship between dysthymia and defence. This will arise from the fact that not only will the stimuli employed be only mildly stressful but also that the individuals used as subjects, even when they are selected as being at an extreme on some personality index, are usually students rather than, say, psychiatric patients.

There are, however, other studies which show the expected U-distribution of results. McClelland and Liberman (1949) showed such difference in threshold for "deprivation" words in subjects showing differences in "n-Achievement," (see Fig. 7.10).

Other relevant studies may be examined under headings provided by the principal factors taken into account in their design, as follows.

LOW STRESS AND PERSONALITY

An experiment by Chodorkoff (1954) used an "accuracy of self-description" test (which has been shown to be related to adjustment by Brownfain (1952)) and a Rorschach estimate of general adjustment to measure the personality variables. This study demonstrated that it was the less adequately adjusted individuals who showed defensive threshold phenomena. Another study by the same author, however, (Chodorkoff, 1956) attempted to relate anxiety to defensive phenomena with a negative outcome. It seems likely that such results are vitiated by the fact that the personality measures in this study were derived from Rorschach indices of very doubtful validity.

A study using a better measure of the relevant personality variables has been reported by Smock (1956a). He used two groups of twenty subjects;

one group chosen on the basis of high scores and one on the basis of low scores obtained on the Sarason Anxiety Scale (Sarason and Gordon, 1953). To estimate the effects of such anxiety on the perception of anxiety-arousing words Smock used a technique similar to that employed by McGinnies and Sherman (1952). The results obtained in this experiment confirm the present hypothesis in two respects. Firstly, anxiety level as measured by the Sarason test was positively associated with delayed recognition of words, and, secondly, the anxiety-arousing properties of the pre-task word also contributed to the elevation of recognition thresholds under all experimental conditions. The interaction which would have been expected on the present hypothesis was, however, not statistically significant.

Kissin, Gottesfeld and Dickes (1957) have also shown that persons who are inhibited (in the sense of "restrained" or "constricted") on projective tests may show raised thresholds for sexual, as compared with neutral words.

Pustell (1956) using shock-associated geometrical figures as tachistoscopic stimuli, found significant threshold differences between male and female students. The males showed vigilance, the females defence. Pustell claims that this was because the males found the shocks moderate, while the females found them severe.

HIGH STRESS AND PERSONALITY

A study which appears to the present author to be illustrative of the situation to be expected on the right-hand side of the postulated inverted U-curve has been reported by Eriksen and Browne (1956). These authors experimentally manipulated the frequency of response strength of ten words for two groups of about twenty student subjects. For one of these groups they arranged that these ten words should also become conditioned stimuli for anxiety (through association with a failure experience). The groups were also divided in terms of high and low scores on the "Psychasthenia" scale of the M.M.P.I. Eriksen and Browne were able to show that while the variables of frequency and recency did, in fact, lower the perceptual recognition thresholds for the experienced words, this reduction was *less* in the case of the anxiety-conditioned words. They were also able to show that the group high on psychasthenia (or in our terms, in dysthymia) had a *lower* mean threshold on this occasion for the anxiety-related words than did the low psychasthenia group. Eriksen and Browne suggest that this difference in thresholds was due to the presumed fact that the failure-associated words were *less* anxiety-producing for the high psychasthenic group. The present writer would suggest, however, that the reverse may be the case and that, in the high-stress area in which

they were operating, the high psychasthenic groups were unable to avoid anxiety mediation and were therefore exhibiting vigilance. This latter interpretation would, in fact, seem to be more consonant with other results obtained by Eriksen (1952*a*, 1954*a*) discussed below (see pages 276 and 277).

Osler and Lewisohn (1954) using the Taylor Anxiety Scale and ingeniously employing paired stimuli as alike as possible, in which the difference in

FIG. 7.10. MEAN RECOGNITION TIMES IN STANDARD SCORES FOR ACHIEVEMENT- AND SECURITY-RELATED WORDS PLOTTED FOR THE UPPER, MIDDLE AND LOWER THIRDS OF THE N-ACHIEVEMENT DISTRIBUTION AS OBTAINED BY COMBINING RANKS ON THE T.A.T. AND ANAGRAMS MEASURES OF N-ACHIEVEMENT

(From McClelland and Liberman, 1949)

one letter alone made them acceptable or unacceptable (e.g., *tit-tot*, *bitch-hotch*), also found *lower* thresholds for the unacceptable words in the high-anxiety group. The opposite difference, which would be predicted on the basis of the present hypothesis for the low-anxiety group, did not, however, appear.

VARIATION IN STRESS

In addition to the studies already quoted (e.g. Lacy, Lewinger and Adamson, 1953; Freeman, 1954, 1955) in which forewarning appears to have *reduced* anxiety, some studies have been made on the effect of the experimental increase of anxiety.

In one experiment which, however, attempted to vary the stressfulness of the task situation, Stein (1952) showed that under conditions of increased anxiety there was an accentuation of either sensitization or defence in twenty-four neurotic patients, rather than the progressive *change* from one to the other which would be predicted from the present hypothesis.

Zuckerman (1954) tried to see whether frustration-induced aggressive need had any effect on the tachistoscopic threshold for aggressive words compared with neutral words in groups of subjects in whom had been induced varying degrees of need-strength.

Higher thresholds were found for the aggressive words but these were not associated with the differing, presumably need-arousing, conditions. However, the experimental group *did* show greater *variability* in threshold phenomena than did the control group.

Blum (1954) demonstrated (in a study whose design, however, has been criticized by Smock, (1956b)) that, by increasing anxiety through two stages, subjects could be induced to show first vigilance and then defence for selected items from the "Blacky Pictures" (Blum, 1950). The author himself interprets these results in terms of two psychoanalytic hypotheses, in which vigilance represents the effect of "the unconscious striving for expression of underlying psychosexual impulses," and defence represents the "warding off of these threatening impulses as they begin to approach awareness." It appears to the present author, however, that Blum's results may be more economically subsumed under the hypothesis advanced in this chapter, which does not invoke the personalized agencies of psychoanalytic theory. A similar interpretation might be made of Nelson's (1955) confirmation of Blum's results. Blum (1957) has also cross-culturally validated these findings on a group of Italian subjects.

CONSISTENCY OF "RESPONSE STYLE"

Evidence for the current hypothesis should not only be traceable in studies which have used the same kind of situation (e.g., visual recognition) and which have attempted to control the relevant variables; further evidence should also be available from studies in which the process of "mediation avoidance" can be said to be at work in quite different kinds of situations.

For example, Blum (1955) has demonstrated relationships between such avoidance in *recall* and in *recognition*. In a situation which controlled the variables of "set," familiarity and selective verbal report, seventeen graduate student subjects were required to recognize tachistoscopically selected items from the Blacky Pictures. In the series of stimuli were included pictures to which the subject had previously shown both conflict and repression (i.e., avoidance tendencies such as forgetting the picture or its name in either of two recall procedures) and neutral pictures. Similar sets of scores were obtained for pictures which were *not* actually flashed (the subjects being unaware of this) so as to control for the actual avoidance within the perceptual situation. As Eriksen (1957) has pointed out, this is a very important kind of control to exercise, since it is necessary to show that the defence type of result is not obtained when subjects are tachistoscopically shown pictures other than the ones which are supposed to portray their conflicts. The results obtained in this experiment can be seen in Table VII.1.

There are an unequal number of subjects within each condition since all seventeen did not have pictures falling into all four conditions, for example, only six

TABLE VII.1
MEAN FREQUENCY OF PICTURE CALLS
(From Blum, 1955)

Conditions	No. of subjects	Mean No. of calls per picture
1. Present pictures (Conflict + repression) .	6	9.42
2. Present pictures (Neutral)	14	17.12
3. Absent pictures (Conflict + repression) .	5	15.20
4. Absent pictures (Neutral)	14	16.69

$t = 3.83$
 $p < 0.001$

 $N.S.$

subjects obtained "conflict plus repression" scores on one or more of the "present" pictures. Blum notes that—

Pictures representing areas of conflict and repression are significantly undercalled when the stimuli are actually present (Condition 1) in comparison to the same pictures unaccompanied by conflict and defence (Condition 2). This difference between disturbing and neutral pictures does not obtain when the stimuli are absent (Condition 3 *v.* 4). . . . Two interesting sidelights also deserve mention. Though the hypothesis deals only with the combined effect of conflict and repression, the data lend themselves to a further breakdown on the effect of conflict alone. Fourteen individuals showed conflict but no defence on present pictures. Their mean number of calls per picture is 17.68, which conforms closely to the chance expectancy. Therefore the conclusion is warranted that an avoidance response cannot be expected solely from the existence of conflict, but requires as an essential component, the predisposition to avoid, namely repression. (Blum, 1955, p. 27.)

Perhaps the best evidence concerning the consistency of response styles, and their relation to stress and personality factors, comes from the work of Eriksen. In one study Eriksen (1952a) compared the effect of individual differences in the response to ego-threat in a situation involving memory for incompleting tasks (*see* pages 280 *et seq.*) with the effect of these individual differences upon the perceptual recognition of ego-threatening stimuli. In the former situation college students were required simply to recall the names of tasks, half of which they had been allowed to complete and half of which they had been forced to leave unfinished. Half the subjects did the tasks under the guise of an intelligence test (i.e., they were made ego-involved, or, in our terms, they were made

TABLE VII.2
MEAN PERFORMANCE OF SUBJECTS AS RELATED TO THE TENDENCY TO SHOW SUPERIOR RECALL
FOR SUCCESSFUL OR UNSUCCESSFUL SENTENCES

(From Lazarus and Longo, 1953)

Group	Learning by trials		Learning by number of correct syllables		Recall in terms of per cent of total*		Relearning by number of trials	
	S†	N	S	N	S	N	S	N
Superior recall of successes	17.1	15.5	28.6	31.1	56.1	74.0	3.12	2.55
Superior recall of failures	15.5	14.9	25.8	30.7	72.1	60.0	2.60	3.34

* This comparison results in a difference between groups by a Chi-square two-by-two analysis which is significant beyond the 0.01 level of confidence.

† S refers to shock syllables and N refers to non-shock syllables.

anxious). The other half did the tasks under much more relaxed conditions. It was found that the main effect of the ego-involvement procedure was greatly to increase the group variance on the recall of completed *v.* uncompleted tasks. That is to say, compared with the non-ego-involved group greater individual differences were apparent.

For the second part of this study individuals were selected from the ego-involved group in terms of their scoring either a high success-to-failure ratio or a high failure-to-success ratio in the recall of tasks. Eriksen then proceeded to determine the relation between association-time (on a word association test) and the recognition thresholds for "complex-indicating" words for these individuals. Comparison showed that individuals who had responded to threat in the first situation by forgetting their failures showed a similar avoidance reaction in their perception of threatening words. On the other hand, those who had a high failure-to-success ratio in the first situation perceived the threatening words as quickly as they did the non-threatening words.

Eriksen (1952*b*) was also able to show that subjects favouring successes over failures in the first type of situation described above also required longer to learn and to relearn paired associates when one of the pair was a word having a long reaction time in a word-association test. On the other hand, the subjects who favoured the incompleting tasks learned words with long association times just as quickly as words with short association times.

Spence (1957), on the other hand, failed to find such consistency in the learning and recognition of failure words. Absolute threshold difference rather than *direction* of difference was related to anxiety in his experiment.

However, Lazarus and Longo (1953) were also able to show that when individuals favouring successes to failures in the recall of interrupted tasks were required to learn and relearn pairs of nonsense syllables, some

of which had been associated with electric shock, then they recalled and relearned a higher percentage of the unshocked syllables. Those who had recalled more failures in the first situation, however, were able to recall and relearn a higher percentage of the shocked syllables (*see* Table VII.2.)

Lazarus and Longo note that—

The primary finding of this experiment is that subjects who recalled their successes in one situation also tended to recall material not associated with painful stimulation in another. This relationship occurs in spite of the fact that the two tasks employed are essentially different and the two experiments which are being compared utilized apparently different kinds of threat (*viz.* failure *v.* physical pain produced by electric shock). It is impossible to account for the correspondence in the performance of the subjects in the two situations in terms of task or ability variables. In order to explain the relationship, it appears reasonable to think in terms of some *intervening process* or some concept like habit or style of responding to threat. (Lazarus and Longo, 1953, p. 49.)

Such apparent "consistency of response" seems to the writer to be of considerable interest since it indicates, as has been noted by a number of authors, including Walton (1957), an important link between avoidance in simple perceptual tasks *and* in more complex ones. It also appears that the common mechanism of mediation avoidance, and similar effects of stress and personality on this mechanism, can also be adduced, for example in the work on memory for incompleting tasks, instances of which have been mentioned above. Such experiments have, of course, been commonly placed under the label of "studies in the Zeigarnik effect," and before the suggested relationships are further explored some of the findings made in this latter area may be briefly discussed.¹

¹ A comparison of thresholds of recognition of normals and schizophrenic patients for neutral and taboo words has been reported by McGinnies and Adornetto (1952). Both groups showed higher thresholds for taboo words. The schizophrenic thresholds were generally higher than the normals for both types of words and they produced more "pre-recognition hypotheses."

STUDIES OF THE "ZEIGARNIK EFFECT"

Description of the Phenomena

In 1927 Zeigarnik reported a series of experiments concerning the performance and recall of simple paper-and-pencil tasks. In these experiments she allowed her subjects to complete some of the tasks but interrupted their performance on others before they had finished them. When they were later asked to recall the names of the tasks Zeigarnik found that most of her subjects recalled more of the uncompleted than of the completed items. This kind of differential recall has been labelled "the Zeigarnik effect."¹ This effect was originally measured in terms of the proportion

$$P = \frac{\text{Number of Interrupted (I) tasks}}{\text{Number of Completed (C) tasks}}$$

and it can be seen that if $P = 1$ then there is no differential preference; if $P > 1$ then the interrupted I tasks are favoured in recall, and if $P < 1$ then the completed C tasks are favoured. The actual means of the ratios obtained by Zeigarnik in one experiment with thirty-two subjects averaged 1.9. This represented an advantage of 90 per cent to the I tasks. In another experiment with different items and fifteen different subjects the mean ratio was 2.0.

Following upon the work of Zeigarnik other investigators have criticized and have attempted to improve upon her methods and techniques.

Pachauri (1935a) argued the importance of better controls in the experimental study of the effect. This author reported a study (1935b) which took into account such variables as the nature and duration of the tasks (showing the longer the task the more likely it was to be recalled), and which also examined the effects of the difficulty of the tasks and the influence of repetition. On the whole, the results of this study were in remarkable agreement with Zeigarnik's original findings; I tasks being recalled on the average 90 per cent better than C tasks.

Other authors who have confirmed Zeigarnik's original findings include McKinney (1935) who studied the effect in relation to maze- and nonsense-syllable-learning; Martin (1940) who examined the effect of the time-span between task completion or incompleteness and recall, and Cartwright (1942) and Gebhard (1948) who studied the effects of interruption on the rated "attractiveness" of activities.

Marrow (1938a, 1938b) used an experimental procedure with thirty subjects and twenty tasks taking

¹ Only the *recall* of tasks will be considered here, although some work has been similarly concerned with the *resumption* of interrupted tasks. Such work has been reported, for example, by Ovsiankina (1928) (see also Rickers-Ovsiankina, 1937), Freeman (1930, 1938), Rosenzweig (1933), Adler and Kounin (1939), Nowlis (1941), and Rethlingshafer (1941a, 1941b) among others.

into account such factors as serial position effect and individual differences in remembering. He was also able to show that the Zeigarnik effect was a function of "experienced failure" rather than of interruption or incompleteness *per se*. He also criticized the kind of ratio used in the first studies and suggested a more adequate measure in the form

$$\frac{\text{Average recalled } I \text{ tasks}}{\text{Average recalled } C \text{ tasks}}$$

De Monchaux (1952) showed that this reduced Zeigarnik's original ratio from 1.9 to 1.6. She also studied the effects on the recall ratio of the relation between item completion and serial isolation; showing the interaction between these factors to be significant.

Variations in the Phenomena

Despite the ample confirmation of the effect achieved by many investigators, certain variations and even contradictions have emerged from other studies. These have been commented upon by Prentice (1944), Boguslavsky and Guthrie (1941), Crafts, Schneirla, Robinson and Gilbert (1950), and Boguslavsky (1951) among others. The main contradiction has emerged from experiments which have found a preponderance of C over I tasks in recall. It should be noted, however, that Zeigarnik herself was aware of the possibility of obtaining such reversals. This happened in an experiment of hers when the subjects were fatigued (1927).

Rosenzweig and Mason (1934) however, secured more recall for C than for I tasks in subjects not suffering from fatigue. They used forty crippled children between the ages of 5 and 14 approximately. The tasks they gave them were jigsaw picture puzzles, and these were presented as a "test" with a prize for the one who did best. Each child was allowed to succeed on half the puzzles he attempted and prevented from completing the other half. At the end of the session each was asked to recall the names of the puzzles attempted. The scores obtained were "recall difference" scores, expressed as percentages from the formula

$$\frac{C \text{ recalled}}{C \text{ given}} - \frac{I \text{ recalled}}{I \text{ given}} \times 100$$

Altogether more C than I puzzles were recalled. The authors found, in fact, that the subjects could be divided into three groups—

- (i) those who remembered more C than I tasks;
- (ii) those who remembered more I than C tasks;
- (iii) those who remembered equal numbers of each.

They also found that those in group (i) were different from those in group (ii) in that they tended to have a higher M.A. and also a higher average rating, as made (fairly unreliably as it proved) by their teachers, in the trait of "pride."

Further work by Rosenzweig showed that this discrepancy with Zeigarnik's original results could be considered due, in part at least, to differences in ego-involvement, or, as the present writer would prefer to say, to differences in the amount of stress in, or to the amount of anxiety aroused by, the test situation. Thus, in one study (Rosenzweig, 1943) sixty college students were each given a series of jigsaw puzzles to solve but were only allowed to finish half of them. One half of these subjects were given the tasks under informal conditions (i.e., non-stressful) which were "task-oriented" in the sense that the experimenter implied that he wanted to find out certain facts about the material used. The remaining subjects had impressed on them that the results would reflect their own ability; that is to say, the conditions were formal, "ego-oriented," stressful, or anxiety-arousing. When the subjects were asked to recall what they had been doing, the results of this experiment, using the notation already described, could be tabulated as follows—

	$P = 1$	$P = .1$	$P = 0$
Informal conditions	7	19	4
Formal conditions	17	8	5

These results not only showed that the relative stressfulness of the situation plays a part in differential recall, but also that individual differences in reaction can be demonstrated.

The effect of such individual differences has received a good deal of attention from Alper. In one of her studies, Alper (1946) examined the general hypothesis that if in the completed-interrupted task situation the group of subjects is *unselected* for personality factors, then the ratio P will approximate unity. The subjects used in this study were twenty undergraduates (ten experimental, ten control). The main experimental tasks were the rearrangement of twenty-four twenty-word scrambled sentences; half of which were solvable in the time allowed and half of which were not. The control subjects were used only to measure performance on the tasks under *informal* conditions. The experimental group, on the other hand, were given twelve of the sentences (some solvable, some not) first under informal conditions, together with other tasks, and, second twelve different sentences (some solvable, some not) under the *formal*, "pseudo-intelligence-test" conditions, together with the other tasks. The control results served to ensure that the two sets of twelve sentences were of comparable difficulty.

For the experimental group it was shown that *fewer* sentences were solved under formal than under informal conditions; in other words, the ego-orienting circumstances were shown to be, in fact, more disrupting or stressful. Actual memory for the sentences was also found to be significantly poorer for the formal than for the informal conditions. There was, however, no significant difference in selective recall *within* the sessions. This finding Alper interprets as supporting the hypothesis that when subjects are unselected for personality factors then there will be no statistically significant difference between the incidental recall of an equal number of C and I tasks.

Alper (1948) then went on to examine two further hypotheses. The first of these stated that under conditions where equal numbers of I and C tasks are to be recalled, then subjects who recall more C tasks will show consistent differences in personality from subjects who recall more I tasks. This hypothesis was tested on the basis of data gathered in the previous investigation. It should be noted that the ten experimental subjects had, in that investigation, been intensively investigated, in terms of personality, at the Harvard Psychological Clinic, along lines similar to those recounted in Murray's *Explorations in Personality* (1938).

The second hypothesis examined by Alper was that the *direction* of selective recall would differ systematically between the formal and the informal situations.

Examination of the data permitted both these hypotheses to be upheld and Alper went on to suggest that the differences found could be explained in terms of "ego-strength." Those individuals characterized as strong egos preponderantly recalled I tasks in the informal situation and C tasks in the formal situation; while the converse was true of those with weak egos. According to the personality investigations conducted, those with strong egos were high on traits like self-confidence and low on dejection and pessimism; the opposite being true of those with weak egos.

Alper notes that—

Two major patterns of selective recall were isolated by studying the recall of the same Ss under two objectively different experimental conditions, a large body of personality data being available for interpreting the behaviour of each S. The recall of incompleting tasks when self-esteem is not objectively threatened is a pattern characteristic of the "strong ego" who needs to protect his self-esteem only when it is objectively threatened. The recall of completed tasks in an objectively non-self-esteem-involving situation and of incompleting tasks when self-esteem is objectively threatened is characteristic of the "weak ego" who can protect his self-esteem only when the threat is not objectively present. (Alper, 1948, p. 135.)

A critical review of these studies by Rosenzweig and by Alper has been written by Glixman (1948) who points out that the type of "recall ratio" used by these authors (i.e., of the type I/C) confounds a number of variables and makes interpretation of their results extremely difficult. For example, any decrease noted in the ratio I/C might be due to (i) a decrease in I task recall alone, or (ii) to an increase in C task recall alone, or (iii) to an increase in I task recall accompanied by a greater increase in C task recall. Glixman advocates instead the use of separate recall ratios for completed tasks $\left\{ \text{i.e. } \frac{\text{Number of } C \text{ tasks recalled}}{\text{Number of } C \text{ tasks performed}} \right\}$ and for incomplete tasks $\left\{ \frac{\text{Number of } I \text{ tasks recalled}}{\text{Number of } I \text{ tasks performed}} \right\}$ which avoids these difficulties.

Such points as he made have been further discussed by Rosenzweig (1952) and by Alper (1952).

Alper (1957) has recently reported further validating evidence for her hypotheses. Two groups of nine subjects were chosen as being, respectively, strong and weak egos. She demonstrated that it was then possible to predict correctly, significantly beyond chance, their ego-group membership from the direction of their recall patterns on I and C tasks over two sessions, one task- and the other ego-oriented.

The Zeigarnik Effect and the Mediation-Avoidance Hypothesis

Relationships between certain of the phenomena elicited in experiments on perceptual defence and recall of completed and incomplete tasks has already been traced (page 276 *et seq.*) for example, in the experiments of Eriksen (1952a, 1952b) and Lazarus and Longo (1953).

Postman and Solomon (1949) have also examined the notion that common motivational principles may govern behaviour in the two situations.

These latter authors conducted an experiment in order to ascertain the speed with which a subject would recognize stimuli representing C and I tasks. The subjects were eighteen students and they were required to solve a series of ten seven-letter anagrams, word-frequency being taken into account. The subjects were stopped, in each case, as soon as half of them had completed any given anagram. After this part of the experiment the recognition thresholds for these words were measured tachistoscopically. It was shown that, for the group as a whole, there was no significant difference in recognition thresholds for C and I tasks. Postman and Solomon note, however, that individual differences were evident in that the greater proportion of their subjects showed a significant difference of sensitivity for one or the other. In fact, this result is not inconsistent with Alper's

notion about the lack of differences which may be expected in such experiments when subjects are *unselected* for personality factors.

An interesting corollary of the suggested connexion between the Zeigarnik phenomena and perceptual defence is that the selective recall noted in the former may be due to faulty *registration*; whereas, of course, the explanation put forward in terms of "repression" usually emphasizes poor *retention*. A recent study by Caron and Wallach (1957) shows that the effects are, in fact, mainly due to selective learning rather than selective remembering.

Following the lead of these experimental attempts to unite these two areas it seems feasible to try to bring them together within the conceptual framework already employed in this chapter.

Since the main hypothesis has been expounded already, it will be sufficient to outline the main points here—

1. The conditions of differential ego-involvement (e.g., "formal *v.* informal" conditions of testing) may be regarded as lying on a continuum of differential stress.

2. The personality variables which are important are those which are related to susceptibility to stress (i.e., neuroticism) and to the development of socialized anxiety (i.e., introversion-extraversion).

It seems likely, therefore, that the relevant dimension described by Alper in terms of a dichotomy of strong ego and weak ego may well be a "continuum" through $NE-NI$.

3. Differential recall may be explained in terms of differences in efficiency of recall in situations of high, as compared with situations of low, stress. This is such that while it may be quite efficient to recall incomplete tasks in a low-stress situation it may be relatively inefficient (i.e., anxiety-provoking) to do so in situations of high stress, where the reduction of such anxiety-mediators may be preferable, while, on the other hand, too great avoidance may also be maladaptive.

These elements, and their interaction, may be represented in the familiar diagram (Fig. 7.11).

As before, the "Low Stress" half of the represented dichotomy is already a situation of differential stress for individuals of differing status on the personality continuum $NE-NI$. At the NE end individuals have not yet begun to initiate the avoidance of mediators involved in the recall of either C or I tasks. For the NI individuals, however, the situation has already come to be one of considerable stress so that they have already begun to suppress the recall of anxiety-producing mediators (i.e., the I tasks).

In the situation objectively involving high stress the NE individuals now avoid the recall of I tasks. Individuals at the NI end, however, have reached and

passed such anxiety-level so that their avoidance behaviour breaks down and *I* tasks again preponderate in their recall.

Consideration of Some Further Evidence

The earliest experiments in the field were founded on theories of Lewin's, so that, implicitly at least, the notion of "personality" has had some part in the interpretation of experimental results. Perhaps the

FIG. 7.11

earliest attempt to relate such results to independent, objective personality measurement was made by Pachauri (1936) who obtained no very conclusive results. More recently, however, studies using various techniques have elicited information which may be interpreted in terms of the hypothesis outlined.

As in the previous section of this chapter the relevant studies may be examined under headings provided by the principal factors taken into account in their design, as follows.

STRESS AND PERSONALITY

Eriksen (1954a) has reported an experiment which is almost equivalent to a direct test of the present hypothesis, which is, of course, fairly similar to his own way of conceptualizing the found relationships. In this study he set out to test three general hypotheses, as follows—

A. That "ego-strength" (measured in this experiment partly by a Rorschach conformity score not unlike that found by Eysenck (1947) to be a fairly good measure of neuroticism) should be *directly* related to the tendency to recall *I* tasks under task-oriented (i.e. "low stress") conditions and *inversely* related to the recall of *I* tasks under ego-oriented (i.e., "high stress") conditions.

B. That "hysteria," as measured by the M.M.P.I., should be inversely related to the recall of *I* tasks under ego-oriented conditions.

C. That "psychasthenia," also as measured by the M.M.P.I., should be directly related to *I* task recall under ego-oriented conditions.

Eriksen himself goes on to cite the relevance of these hypotheses to Eysenck's dimensional analysis of personality.

In fact, as can be seen from Table VII.3, the results of his experiment show, in line with the hypothesis advanced, that the *less* introverted the individual the more *I* tasks will he recall in a non-stressful situation; whereas the more *C* tasks will he recall in a stressful situation.

TABLE VII.3
CORRELATIONS BETWEEN THE EGO-STRENGTH
SCALE AND COMPLETED-INCOMPLETED
TASKS RECALL SCORE FOR THE EXPERI-
MENTAL AND CONTROL GROUPS

(From Eriksen, 1954a)

	Experimental (ego-oriented)	Control (task-oriented)
N	43	19
r	- 0.60	0.38
p	0.001	0.055

Analysis of the results of this experiment also showed that the higher the individual scores on the hysteria scale the *less* will be the tendency for him to recall more *I* tasks in the threatening (i.e., high stress) situation. Also, before neuroticism was partialled out of the psychasthenia score, the higher an individual's score was on this scale, the *greater* was the tendency to recall relatively more *I* tasks in the threatening situation.

Another study by Jourard (1954) failed to discover consistent relations (in terms of his own hypothesis) between certain Rorschach responses which were taken as measures of ego-strength and the recall of *I* tasks. However, the hypothesis outlined above would produce almost the opposite expectations from those predicted by Jourard. Thus, in terms of the notions outlined above, the present writer (like Alper) would expect little or no significant difference between the recall of *I* and *C* tasks in a population unselected for personality variables (since individual differences would tend to reduce the mean difference). Jourard, on the other hand, did predict differences, but his results were not in accord with his own prediction. Also, since the tests used were presented under formal, intelligence-test (and hence presumably stressful) conditions, the present author would predict that the

strong egos would recall more *C* tasks, unlike Jourard, who predicted that they would recall more *I* tasks. In any case the Rorschach indices used by Jourard in this study have never been validated, whereas the one used by Eriksen (1954a) as has already been pointed out, was very similar to that derived from the multiple-choice Rorschach, which has been shown to be a valid test of neuroticism. It is therefore hardly surprising that Jourard was unable to report any consistent results arising from his study.

Two studies have been reported using the "Schneider index" which is an index of neurocirculatory efficiency, found to be low in neurotics, the results of which agree with the current hypothesis. Thus, Abel (1938) showed that, in a low stress situation requiring the recall of *I* and *C* tasks individuals with high Schneider indices (i.e., good neurocirculatory efficiency) recalled more *I* tasks, whereas those with low indices recalled more *C* tasks. Strother and Cook (1953) using the same index report results in striking agreement with Abel's in the performance of a test under conditions of differential stress. Those individuals with high neurocirculatory efficiency tended to show a gain in performance under conditions of increased stress while those with low efficiency showed a marked decrement.

The reaction to frustration, as represented by the Zeigarnik situation, has been explored by Rosenzweig and Sarason (1942) and Sarason and Rosenzweig (1942). These authors were concerned to evaluate Rosenzweig's "triadic hypothesis" which he had enunciated as follows: "Hypnotizability as a personality trait is to be found in positive association with repression as a preferred mechanism of defence and with impunitiveness as a characteristic type of immediate reaction to frustration," (Murray, 1938, p. 489).

The main measure of "repression" which these authors employed was the differential recall of *I* and *C* tasks in a situation of fairly mild stress. They were able to show that the correlations between the forgetting of *I* tasks and suggestibility (as measured by the "Body Sway" apparatus) in two groups for whom both these measures were available was 0.25 and 0.47 respectively. For another group for whom a correlation was obtained between forgetting of *I* tasks and ability to be hypnotized the correlation was 0.66.

Atkinson (1953) and Atkinson and Raphelson (1956) studied the relationship between "n-Achievement" as measured by responses to the T.A.T., to differential recall of *I* and *C* tasks under conditions differing in stressfulness. From previous formulations regarding the processes of socialization it is to be expected, on the present hypothesis, that those highest on n-Achievement will, in fact, be those individuals nearer the *NI* end of the *NE-NI* continuum. The

results of these experiments show that those subjects high in n-Achievement do, in fact, show an increasing tendency to recall more *I* tasks as stress increases and that the opposite is true of subjects low in n-Achievement who, as stress increases, tend to recall fewer *I* tasks. In addition, and again in line with the predictions of the present hypothesis, under conditions of relaxed orientation (i.e., low stress) the low n-Achievement group recalled *more I* tasks than the high n-Achievement group under the same conditions although the difference was only "near significance."

The present hypothesis is further confirmed by Alper's (1957) demonstration of an *inverse* relationship between n-Achievement and ego-strength in a group of twenty-eight college leaders.

VARIATIONS IN STRESS

Some studies have paid attention only to stress variables, ignoring factors of personality. Differences in the recall of tasks would only be expected in such cases if the subjects used were fairly homogeneous in terms of personality since, as Alper has suggested, the results of heterogeneity may be to cancel out differences.

Most of the studies have been, in fact, carried out on normal undergraduates and it would therefore be expected, in terms of the present hypothesis, that, overall, an increase in stress would produce the recall of a preponderance of *C* tasks, since most of such studies operate in the area of low-stress.

Such results have been reported by Walsh (1940, 1942) who investigated, in several experiments, the differential recall of various groups of school children. On the whole most of the work confirmed Zeigarnik's main finding, her general *I/C* ratio being 1.7. In view of the present hypothesis, however, it is interesting to note that one of the principal occasions when this ratio fell below unity, indicating superior recall of *C* tasks, was just after an air-raid when the children had been under considerable strain.

Lewis (1944) showed, in an experiment with fourteen students, each working with a "planted" co-worker in an "informal atmosphere," that co-operative completion was as good as "self-completion" so far as differential recall was concerned. She also went on to show (Lewis and Franklin, 1944) that an increase in stress (i.e., through ego-orientation) resulted in the recall of more *C* than *I* tasks.

A report by Sanford and Risser (1948) showed that, when twenty-five mothers were tested in the presence of their daughters, and were failed on six out of fifteen difficult tasks, recall produced a preponderance of *C* tasks. It should be noted that most of these women found the proceeding very embarrassing. A somewhat similar experiment with children, on the other hand, produced recall preponderance of *I* tasks,

but the circumstances of administration were not nearly so stressful. Sanford and Risser conclude that such "self-defensive forgetting" is likely to occur when the need to regain self-respect is greatest and the possibility of doing this by constructive striving is at its lowest.

Glixman (1949) examined the recall changes for *I* and *C* tasks as a function of stress. This author showed in an experiment with college students, under three different degrees of anxiety arousing situation, that as stress increases the recall of *I* tasks decreases. He also showed, however, that there was no significant increase in the number of *C* tasks recalled with increase in stress. In another article (1948) he has presented his results as follows (see Table VII.4)—

TABLE VII.4

MEANS FOR RECALL RATIOS FOR COMPLETED AND INCOMPLETED TASKS AND FOR THE RECALL DIFFERENCE SCORE OVER SITUATIONS I, II, AND III, AND THE *F*-VALUES ASSOCIATED WITH VARIATIONS AMONG THE MEANS

(From Glixman, 1948)

	Situation I	Situation II	Situation III	<i>F</i>	<i>F</i> at 5 per cent
Recall Ratio: <i>C</i>	0.60	0.62	0.52	2.44	3.13
Recall Ratio: <i>I</i>	0.57	0.52	0.44	3.42	3.13
Recall Differences	0.03	0.10	0.08	0.50	3.13

These results can also be represented graphically, see Fig. 7.12.

FIG. 7.12. MEANS FOR RECALL RATIO FOR COMPLETED AND INCOMPLETED TASKS AND FOR THE RECALL DIFFERENCE SCORE SITUATIONS I, II and III

(From Glixman, 1948)

This table and graph show clearly that, as the stress increases so the recall of *I* tasks decreases. There can also be seen a tendency, as stress increases, for fewer tasks altogether to be remembered and for a greater proportion of these to be *C* tasks.

The greater recall of *C* tasks under conditions of stress has also been confirmed by Kendler (1949) in a situation in which twenty-two college students were given sixteen jigsaw puzzles as an intelligence test and their recall compared with that of ten students given the same puzzles under neutral conditions. The former remembered more successful than unsuccessful tasks, to a significant degree, whereas the latter remembered more, though not significantly more, unsuccessful tasks.

Hays (1952) found that the effect, suggested here to be a function of stress, could be produced by interpolating a complex rather than a simple task between performance and recall.

Smock (1956) demonstrated differential recall of

C and *I* tasks under different instructional conditions as shown in Fig. 7.13. He was also able to show that, under both conditions, recall of stimuli selected as likely to arouse anxiety were recalled to a lesser degree than were the neutral stimuli.

FIG. 7.13. FREQUENCY OF RECALL OF COMPLETED AND INCOMPLETED TASKS AS A FUNCTION OF INSTRUCTIONAL CONDITIONS

(From Smock, 1956)

An interesting cross-cultural verification of the effects of stress comes from a study by Ito (1957) who obtained with Japanese subjects the kind of results predicted.

As well as attempting to encompass such additional

evidence, the present formulation enables the resolution of an apparent discrepancy between the findings of Rosenzweig and Mason (1934) on the one hand, and those of Sanford (1946) on the other. It will be recalled (see page 278) that Rosenzweig and Mason found among their crippled children subjects that those of greater maturity tended to remember more *C* than *I* tasks. Sanford, however, using normal children, found the reverse, namely that those of more advanced M.A. tended to remember more *I* than *C* tasks. It should be noted, however, that in the first study the tasks were set under formal, test-like, competitive and presumably stressful (or ego-orienting) conditions, whereas in the second study the tasks were given under much less stressful conditions. Thus, if we suggest that those who appeared to be of greater maturity in each study were those nearer the *NE* end of the *NE-NI* continuum, then, given the differential stress, the results are as predicted by the present hypothesis and the contradiction vanishes.

One of the few studies examining the effect of *recall* of completed and uncompleted tasks in psychotic individuals is that by Winder (1952) who reports that while paranoid schizophrenics tend to recall more *I* than *C* tasks, non-paranoid schizophrenics show a slight but significant tendency to recall more *C* than *I* tasks.

Another study, by Tamkin (1957), showed that a group of schizophrenic subjects remembered more *I* than *C* tasks under ego-involved conditions.

It may be claimed, therefore, that in situations in which the anxiety component is provided by failure experience we find results which are consonant with

the hypothesis originally elaborated to relate findings in the adjacent field of perceptual defence.

Credence is further lent to this hypothesis by its ability to relate certain facts within this new area which at first seemed quite contradictory one to another.

It will be of considerable interest to see if the same hypothesis can be extended to relate together data from yet another adjacent area, namely that comprising studies in the phenomena known by the label of "Level of Aspiration." The tasks which are commonly used to elicit such phenomena are, of course, concerned to provide experience of performance in situations of success and failure so that it would seem reasonable to expect the current hypothesis to apply, at least in part.

Such a link has explicitly been suggested by Eriksen who notes that—

Eysenck reports that in level-of-aspiration experiments Ss high on the extravertive pole tend to overestimate their performance and are little bothered by failure, while Ss falling on the introvertive pole tend to underestimate their performance and are preoccupied by failure. Such reaction to failure and threat would, at least superficially, seem to be related to differential memory for completed and uncompleted tasks. By emphasising the successful tasks and ignoring the failed ones, extraverted Ss would be expected to recall relatively more completed than uncompleted tasks, while for the introvertive Ss the tendency would be reversed. (Eriksen, 1954, p. 49.)

Some aspects of level of aspiration studies may now be considered.

STUDIES OF LEVEL OF ASPIRATION

Description of the Phenomena

The first reference to "level of aspiration" to appear in the literature was in a study which used the concept only incidentally. Dembo (1931) used the term "momentary level of aspiration" in an experimental study of anger, and Hoppe (1930) next took over this concept and experimented with it, being especially interested in the relationship between goal-setting and the feelings related to experience of success and failure.

The first objective definition of the notion, however, was provided by Frank, who defined it as: "*... the level of future performance in a familiar task which an individual, knowing his level of past performance in that task, explicitly undertakes to reach. By level of past performance is meant the goodness of the individual's past performance, as he knows it.*" (Frank, 1955a, p. 119.) The last phrase of this definition covers

the fact that the subject may, in certain experiments, be given a false score.

Rotter (1942b) has mentioned seven characteristics which such a task should have: it should be (1) novel, (2) neither too easy nor too difficult, (3) neither have too wide a variance, nor (4) be too stable; it should be (5) interesting, (6) not much influenced by learning, and, finally, (7) be convenient and adaptable. To these considerations Eysenck (1947) adds the suggestion that it should (1) show moderately high correlation between successive trials, so as to permit fair anticipation of future scores and that (2) success as shown in scores should not be too readily evaluated by the subject himself, but only by the experimenter.

Gardner (1940b) and Rotter (1942a) have further critically examined the use of the notion and methods employed for its study.

Eysenck (1947) has described in some detail one

piece of apparatus which has been used to derive level of aspiration scores. This is the "Triple Tester," which, he says, is—

An adaptation of the pursuit meter, constructed by the late Dr. Craik of Cambridge University. The apparatus consists of a brass drum carrying an ivory cover, rotating towards the subject. This ivory cover is marked out as a helical "road" with holes punched in it. A "vehicle" in the form of a bronze ball moved sideways on a rack is steered along this road by a steering wheel. The purpose is to keep the ball on the line of holes; each "hit" is scored on an electric counter. The steering wheel operates the rack through an integrating gear instead of directly. Instantaneous deflection of the vehicle from its path is impossible with this method of transmission, and the subject is forced to anticipate the necessary moves. The more he anticipates, the smoother will be the path which he describes, whereas rapid movements made at the last moment will result in violent oscillation or wobbling of the vehicle which requires correction and leads to still worse scores. The test resembles in some ways the penny-in-the-slot machines seen at fun-fairs and has a certain fascination for most subjects which often makes them loath to abandon the machine after the testing session is over. (Eysenck, 1947, p. 129.)

A variety of other devices has, of course, been employed, prominent among them being the so-called "Aspiration Board" devised by Rotter (1942*b*). Some idea of the range of other methods employed may be gained from column 3 of Table VII.5.

The main "primary" measures which can be derived from such situations are represented in Fig. 7.14, which has been adapted from a figure provided by Lewin *et al.* (1944). For example, in the "Triple Tester" task described above, the Judgement Discrepancy (J.D.) is obtained as follows: after a few practice runs the subject may be told what the best possible score is and then given his initial test trial. He is then asked what he thinks his first score was. The difference between his actual score, and his judgement of it constitutes a J.D. score. He is now told his actual score and is then asked to say what he will get next time. The difference between this estimate and his past actual performance is his Goal Discrepancy (G.D.) score. The difference between what he says he will get next time and what he actually does get is his Attainment Discrepancy (A.D.) score.

Other secondary measures which have been used include the *Affective Discrepancy*, or difference between G.D. and J.D.; the *Index of Flexibility*, the sum of all shifts made in level of aspiration throughout the test, and the *Index of Responsiveness*, or the measure of typical response, i.e., the number of times bids are raised after success, and lowered after failure.

More detailed examination has been accorded to scoring practices and the measurement of interrelationships by Preston (1942), Lezak and Raskin (1950), Sutcliffe (1952*a*, 1952*b*, 1955), and by Siegal (1957), who relates the phenomena to a theory of games model.

It is evident that the notions employed can only be useful in so far as they have some kind of generality. They must, for example, be relatively independent of the actual tests employed. Examples of the range and

FIG. 7.14

J.D. = Judgement discrepancy

= Difference between what you did get and what you then think you got

G.D. = Goal discrepancy

= Difference between what you did get and what you think you are going to get

A.D. = Attainment discrepancy

= Difference between what you think you are going to get and what you do, in fact, get.

(After Lewin *et al.*, 1944)

types of generality which have been found are given, in chronological order, in Table VII.5.

As Eysenck has pointed out in his review: "The actual size of the correlation would appear to depend upon three points—

1. The similarity of the two tests, as regards the ability measured.
2. Similarity of the scale on which goodness of performance is measured.
3. Similarity of the experimental situation, i.e., whether the two tests are given in the same experimental session or not." (Eysenck, 1947, p. 133.)

Differences in aspiration expressions have also been noted between situations using different kinds of instructions. For example, Frank (1937) found that the achievement of subjects who were asked, "What do you think you will do?" were likely to be closer to their guesses than those who were asked, "What do you intend to do?" Festinger (1942*a*) also found that discrepancy scores of subjects who were asked, "What score would you like to make next time?" were likely to be significantly higher compared with those of subjects who were asked, "What score do you expect to get next time?" The influence of different kinds of instructions has also been examined in other studies (Preston and Bayton, 1941, 1942;

TABLE VII.5
SOME MEASURES OF THE GENERALITY OF LEVEL OF ASPIRATION PHENOMENA
(CHRONOLOGICAL ORDER)

Authors	Date and subjects	Tasks	Measures	Generality		
				1. Split-half: series of trials in one session	2. Test-retest: one experimental session to another	3. Intercorrelations over a variety of tasks

Irwin and Mintzer, 1942; MacIntosh, 1942; Irwin, 1944; Preston, Spiers and Trasoff, 1947; Diggory, 1949; and Bayton and Whyte, 1950).

Variations in the Phenomena

From the beginning most studies have demonstrated high "Indices of Responsiveness" in most subjects. That is to say, the most "typical" responses have involved raising aspirations after success and lowering them after failure. For example, Jucknat (1937) showed that, in the case of children's performance on a maze task, 76 per cent shifted their aspirations upward following success and 84 per cent downward following failure.

However, besides such "typical" reactions, variations in level-of-aspiration phenomena have been described in the literature from time to time and it is these latter results which are of most interest in the present context. Such phenomena may be considered under two main headings—

(a) variations due mainly to *environmental* factors (principally changes in environmental stress) and

(b) variations due mainly to *personal factors* (principally differences in *susceptibility* to stress).

ENVIRONMENTAL FACTORS

This category may itself be subdivided as follows—

(i) *The Effect of "Reference Scales"*

It has been shown that the expressions of level of aspiration may be altered by making the subject aware of the status of his performance, either in relation to his own group (Anderson and Brandt, 1939) or in relation to members of other groups. An example of the latter kind of study is provided by Chapman and Volkmann (1939). These authors were able to show an inverse relation between level of aspiration and the social prestige value of the reference group. They gave eighty-six students a multiple-choice test of literary knowledge. These subjects were divided into four groups: (1) control subjects, who were given their own scores as a base-line for their aspirations; (2) subjects who were given their scores in terms of a comparison with a fictitious group of "literary critics"; (3) subjects given their scores in comparison with a fictitious group of students; (4) subjects given their scores in terms of a comparison with a group of "workers." The lowest discrepancy scores were obtained in the case of group 2, next for group 1, then for group 3, and the highest were obtained for group 4. That is to say, comparison with the "worker group" produced most "challenge to self-esteem," resulting in higher discrepancy scores. Similar effects of differential social prestige have been

observed elsewhere (Hertzman and Festinger, 1940; Gould and Lewis, 1940; Preston and Bayton, 1941; MacIntosh, 1942; Festinger, 1942*b*; and Hansche and Gilchrist, 1956). The effect of "intellectual prestige" has been neatly demonstrated by Gilinsky (1949). She attempted to make the position of the comparison group more precise in relation to the individual. Ten groups of ten students were each told the (fictitious) average I.Q.s and average scores of another group of students. They were then asked to state their I.Q. and

FIG. 7.15. ASPIRATION LEVEL AS A FUNCTION OF PERCEIVED DIFFERENCE IN ABILITY BETWEEN THE INDIVIDUAL AND THE COMPARISON GROUP

(From Gilinsky, 1949)

their level of aspiration on the test. The results (see Fig. 7.15) demonstrated that the greater the perceived difference in ability between the individual and the group, the further the level of aspiration diverged from the group norm.

(ii) *Social Factors*

Gould (1941) divided eighty-one students into two extreme groups showing high and low discrepancy scores respectively on six different tasks. She was able to show that members of the low discrepancy group had better economic and social backgrounds than the high discrepancy group. The author suggests that the latter group are subject to more social and economic stress than the former. A similar difference in social circumstance has been found between high and low discrepancy groups by Klugman (1948).

Differences between the sexes have been explained on similar grounds; less social pressure is put on women to "get ahead" so that they find a goal-setting situation less stressful. Smaller discrepancy scores for female normal and neurotic subjects have been reported by Himmelweit (1947), for negro women by Sumner and Johnson (1949), for schoolgirls by Walter and Marzolf (1951), and for female stutterers by Sheehan and Zelen (1955). Bruner and Rotter (1953) found differences in "shifting behaviour" between male and

female Navaho Indians, the males shifting significantly more often. This difference was not confirmed in a study by Himmelstein (1956) on white Americans.

That such social differentials may result in part, at least, from parental influence is demonstrated in a study by Little and Cohen (1950) who showed that a group of thirty asthmatic children who set high positive goals, compared with control children, had mothers who also set high positive goals for them, compared with the mothers of the control children.

(iii) *Success and Failure*

The effect of failure-stress *within* the experimental situation has been examined by several authors.

Sears (1940), for example, studied the effects of success and failure on the goal discrepancy scores of thirty-six school children performing reading and arithmetic tasks. She was able to show that under failure-stimulated (and therefore presumably more stressful conditions) there were, generally, larger discrepancy scores and also greater variability of discrepancies.

Steisel and Cohen (1951) also showed, in a study using forty students, that while the level of aspiration itself decreased markedly following severe failure, the discrepancy scores for their subjects under this condition were extremely high and positive. Somewhat similar results have been reported in a study of fifty students by Ausubel and Schiff (1955). They note that goal discrepancy scores were significantly more positive after cumulative than after variable failure.

PERSONAL FACTORS

The earlier workers who were concerned with level of aspiration phenomena, such as Hoppe (1930) and Frank (1935*b*) mainly attempted to *deduce* personality traits from the phenomena rather than to try to relate these effects to independent measures of personality. The first attempts to do this failed to show significant results. Gardner (1940*a*) using a digit-symbol substitution test on fifty-one adolescent subjects, correlated a version of the G.D. measure with ratings made on the subjects' personality traits by four independent judges. When the correlations between these variables were examined none were found to be significant. Gould and Kaplan (1940) correlated the G.D. scores of eighty-two students on various tasks with certain personality variables, including extraversion as measured by Guilford's S, E and M scales; only insignificant relationships were found.

Sears (1941) however, found more promising results in a further examination of data secured (Sears, 1940; *see above*) in her study of school-children under conditions of success and failure. She made what amounted to further "clinical" assessments or ratings of various discrepancy groups (these

were composed respectively of individuals showing low-positive, high-positive and negative discrepancies). At this descriptive level she found that the low-positive group were well adjusted socially, confident, adaptable, well oriented. The high-positive group, on the other hand, were not very well adjusted socially, tense, insecure, worried. The negative discrepancy group showed strong social reactivity and desire to impress others.

There is a suggestive relationship between these findings and Jucknat's (1937) earlier work. The latter author had three groups of subjects divided in terms of their school work into good, medium and poor students. The poor students tended to show either very low, or very high, aspirations, compared with the other two groups.

Contrary evidence, however, comes from a study by Hanawalt, Hamilton and Morris (1943) who found, in a study of forty college women, that it was the leaders and dominant individuals who tended to have the higher discrepancy scores.

Other workers have discriminated "patterns" of scores in which very high or very low discrepancy scores appeared to be related to personality difficulties. These include Gruen (1945) who found that, in adolescents, the maladjusted subjects tended either to keep their estimates *below* performance level or to make gross compensatory over-estimates. Ax (1947) divided twenty-five subjects into two groups, the "better integrated" and the "less integrated." The second group fell into two subgroups, one of these with high positive aspiration scores the other with large negative discrepancy scores. Klugman (1947, 1948) has reported positive correlation between a Psychosomatic Inventory and discrepancy scores, which he interprets as indicating that the more stable individuals tend to have lower discrepancy scores.

An interesting study by Berkeley (1952) related level of aspiration behaviour, on the Rotter Aspiration Board, to the activity of the adrenal cortex as measured by 17-ketosteroid excretion. He found the greater discrepancies were related to increase in steroid excretion (multiple $R = 0.70$). This author writes that: "The . . . response, in which a wide discrepancy is maintained between aspiration and achievement, is the response of the individual who is stressed by the situation, as indicated by increased activity of the adrenal cortex." (Berkeley, 1952, p. 448.) Cohen (1954) studied the relation, in fifty patients in a general hospital, between goal-setting behaviour and feelings of self-acceptance. He showed that there was a curvilinear relationship between the two; both very high and very low goal-setting being related to self-rejection, only those who could accept themselves were able to set low positive goals.

Bills (1953) and Steiner (1956) also report studies

concerned with relations between self-rating and level of aspiration behaviour.

Level of Aspiration and the Mediation-Motivation Hypothesis

It remains to be seen whether the level of aspiration phenomena already presented can be systematized in relation to an extension of the explanatory hypothesis already put forward in this chapter.

An attempt has been made to relate various performance and personality aspects diagrammatically in Fig. 7.16.

ASPIRATIONS

It can be seen from this figure that there has been added to the conceptions which have so far been used another variable which is a curvilinear function related to the setting of the levels of aspiration with increase in anxiety (induced, for example, by experience of failure).

This notion derives plausibility from the findings of Steisel and Cohen (1951) who demonstrated that, whereas failure experiences were in general followed by *lowering* of the level of aspiration, this level, under several degrees of failure, does not continue to be reduced proportionately, thus resulting in *increase* in discrepancy scores with increasing failure. Similarly, Rao (1954) showed that the *rate* of decrease in level of aspiration, with an increase in the duration of failure stress, was not constant, but became negligible after a certain point.

JUDGMENTS

It can be seen that this aspect of level of aspiration performance is held to be in accordance with the relationships presumed in the examination of the phenomena of both perceptual defence and the Zeigarnik effect.

Thus, at low levels of stress, recall is fairly indiscriminate. At moderate stress level it is focused on success mediation as an anxiety-reducing technique, which then at high stress levels breaks down, once more admitting the anxiety-mediating self-produced stimulation which in turn increases anxiety level even further.

PERFORMANCE

The evidence for the application of the "Yerkes-Dodson effect" to motor performance has been adduced elsewhere (*see* Chapter 2, by Yates).

The notion of a set of curvilinear relationships between performance and aspiration has previously been propounded by Holt (1946). This author points out that, "Bayton (1943) found some positive relation between levels of aspiration and achievement in the more ego-involved of two tasks, with previous

performance held constant. Yet when, in line with his suggestion, ego-involvement was increased considerably in this experiment, the relation fell back to zero. I have been able to reconcile his results and mine only by the hypothesis of a curvilinear relation between the degree of ego-involvement in a task and the extent to which levels of aspiration measure achievement

FIG. 7.16

motivation." (Holt, 1946, p. 412.) Holt describes this hypothesis in terms of three propositions—

“1. When ego-involvement is minimal, levels of aspiration have little motivational significance, being primarily rational judgments.

2. When ego-involvement is present but at low intensities, levels of aspiration have little defensive meaning, but reflect to some extent the intensity of motivation.

3. When ego-involvement surpasses a certain limit, defensive considerations become paramount, and the level of aspiration becomes more complexly determined.” (Op. cit., p. 412.)

The same author (Holt, 1945) had previously reported a study in which after it had been empirically determined which of the two tests was the more ego-involving, subjects were given two level of aspiration

tests. When he examined the correlation between aspiration and improvement for the less involved tasks the correlations were significant and *positive*. On the other hand for the more stressful task this correlation became *negative*.

FIG. 7.17
(From Eysenck, 1947)

It is suggested that the relationships postulated in diagram Fig. 7.16 can take into account this reversal of correlation.

Consideration of Some Further Evidence

In the case of the level of aspiration phenomena and their relation to personality, data are available which constitute a direct test of the hypothesis advanced. It should be noted, however, that such studies have commonly provided a good deal of stress and the results mainly lie in the right-hand area of the proposed "stress dichotomy" (Fig. 7.16). Eysenck and Himmelweit (1946) have reported on certain relations between level of aspiration phenomena and the introversion-extraversion dichotomy as defined by two groups of fifty neurotic patients, dysthymics and hysterics respectively. The situation employed the "Triple Tester" described above. Although the two groups were quite comparable in age and intelligence, as well as in actual performance on the test, striking differences emerged in, for example, the G.D. and J.D. measures (Fig. 7.17).

As can be seen from the above diagram, dysthymics' aspirations are significantly higher, compared to performance, than are the aspiration scores of the hysteric group; also the judgement scores of the dysthymic group are significantly lower, compared to performance, than are the judgement scores of the hysterics. Similar differences have been reported for such groups by Himmelweit (1947) on a different test.

Differences between neurotics in general and normals in general have also been reported by Himmelweit. The principal difference between these groups lay in

the fact that the actual performance of the normals was significantly superior to that of the neurotics. Some of the most interesting results obtained, however, were concerned with *relationships* between various kinds of scores. For example, whereas the correlation between G.D. and J.D. scores was significantly *positive* for the normal groups, it was significantly *negative* for the neurotic groups. That is to say, while the members of both the neurotic and normal groups tended, on the whole, to overrate their future performance and underrate their past performance, in the normal group those who overrated their future performance more than others tended to underrate their past performance less. In the neurotic group, on the other hand, those who overrated their future performance more than others also underrated their past performance more. The findings of this study, in relation to the normal group, is in accordance with the results obtained by Hilgard and Sait (1941) who tested fifty students on a card-sorting and on a pursuit-learning task. In the case of

FIG. 7.18

both these tests the correlations, for this normal group, between G.D. and J.D. scores were significant and positive.

Given the relationships expressed between aspirations and recall, or judgement, expressed in Fig. 7.16, however, it may be suggested that the reversal of the

sign of the correlation noted by Himmelweit may be a function of the part of the curve at which the various groups lie, as shown in Fig. 7.18.

Studies of the performance of psychiatric groups conducted independently of the above findings have been reported. For example, Hartogs (1949) studied the level of aspiration in two hundred and fifteen cases of anxiety neurosis and found an unduly high initial level in 81.2 per cent of these cases. Miller (1951) tested five groups of twenty-five patients including one group of conversion hysterics, one of neurasthenics, one of character disorders, one of paranoid schizophrenics and one of normal controls. On the basis of their G.D. scores on the Carl Hollow Square test Miller was able to divide these subjects into three groups. The neurasthenics, whom Eysenck would, of course, call dysthymics, obtained high discrepancy scores, while the character disorders and hysterics (i.e., neurotic extraverts) fell together with low discrepancy scores, the normals falling in between the two. Ausubel, Schiff and Goldman (1953) also found significantly higher level of aspiration and goal tenacity scores in a high-anxiety as compared with a low-anxiety group of college students in performance on a stylus maze test. A study by Raifman (1957) also suggests that patients suffering from peptic ulcer, who are commonly conceived as over-driven personalities, also show high goal-discrepancy scores.

Confirmatory data from normal subjects has also been provided by Gately (1954) who found level of

aspiration behaviour was related to extraversion-introversion measures obtained from analysis of questionnaire and projective measures of personality. Here again the introverts showed the higher discrepancy scores.

Results on level-of-aspiration measures have also been obtained for abnormal groups of other kinds. So far as psychotics are concerned Escalona (1940) showed that manic patients demonstrated greater "mobility" than did depressed patients and were also more sensitive to success and failure. Miller (1951) found the scores of paranoid schizophrenics to lie nearer his normal control groups than did the groups of conversion hysterics, character disorders or neurasthenics. Winder (1952) found that paranoid schizophrenics showed positive, and non-paranoid small negative, discrepancy scores on a pursuit-rotor task. Jost (1955) found differences between a group of twenty-nine normal subjects and twenty-nine schizophrenics, carefully matched for age, occupation and education. The schizophrenics showed significantly higher reaction-times and frequency of high goal discrepancies. The response score mean on the other hand, was lower for the schizophrenics; they also forgot to make verbal statements of their goal more often than the normal subjects.

Level-of-aspiration phenomena have been examined in epileptic subjects by Arluck (1941) and in mentally defective persons by Shaw and Bensberg (1955), but in neither case did very striking results emerge.

CONCLUSION

A review of the results secured by various investigators in three adjacent experimental areas suggests that certain common elements may be distinguished in them.

An attempt has been made to trace the relationships in terms of interactions between stress and the susceptibility to stress, and the effect of such interactions upon mediation-avoidance behaviour.

The kind of investigations which have been considered form part of that body of data associated with the label ego-function. This examination of the literature has been conducted from that point of view which regards such a label as referring merely to one *kind* of behaviour rather than to a *source* of behaviour, as seems to be implied by some writers (e.g., Allport, 1943) or to an "upper member" in some hierarchy of behaviour, as seems to be suggested, for example, by McDougall (1936) in his notion of the "self-regarding sentiment."

In common with the general policy of this text attention has been focused on interrelationships

among psychological data. Over twenty years ago J. McV. Hunt pointed out that—

Almost blind acceptance of existing nosology has also been an unfortunate tendency (i.e. in psychological experiments with disordered persons). All too frequently this has led to the vain hope of supplying the psychiatrist with rule-of-thumb diagnostic tests for his own categories of disorder. As most of these diagnostic categories have been derived from rough clinical observation of gross symptoms, usually without even statistical check, they should not remain dogma. The experimental psychologist must proceed critically in his use of diagnosis. He should attack problems independently, achieving his own psychological classification inductively from experimental results. (Hunt, 1936, p. 47.)

The attack on "real life problems," through such inductive principles as have been presented, has, as yet, hardly begun; although, for example, Kleinman (1957) has attempted to relate the conceptions of perceptual defence to the phenomena of "psychogenic deafness." It may be hoped, however, that the practice of clinical psychology may benefit from such an

approach to abnormal psychology at least as much as it has benefited from an uncritical acceptance of psychiatric models.

CHAPTER 8

Heredity and Psychological Abnormality

JAMES SHIELDS and ELIOT SLATER

In this chapter we shall consider how far the concepts of heredity can be used to explain some of the psychological abnormalities which have been described in this book. We are not speaking here of social heredity, in the sense in which a kingdom or a family business may be said to be hereditary. Our concern is the differences between individuals which arise from differences in their genetical make-up; and in this sense the hereditary are distinguished from the environmental causes of variation. (Genetical and environmental factors interact with one another, and can never be completely disentangled.) But by appropriate techniques it is possible to estimate how much of the total variance observed in a group of individuals, sharing a common environment, is contributed by genetical causes, though we are not thereby entitled to assume that the contribution would be the same if either the genetic constitution of the group, or the environment, were significantly changed.

Principles of Heredity

Before trying to deal with the extent to which psychological abnormalities may be said to be genetical, we must describe briefly the physical basis of heredity and what we know of the genes and their mode of action. In so far as psychological differences between individuals are genetically caused, they must be due to such differences between genes, i.e. to differences of a physical kind.)

THE NATURE OF THE GENE AND ITS EFFECT ON DEVELOPMENT

(The basic units of heredity are the genes. Chemically, they are thought probably to take the form of very large and elaborately constructed molecules of deoxyribonucleic acid (DNA). Fig. 8.1 may give some idea of the complexity of these molecules. Unless altered by mutation, the genes are transmitted from one generation to the next unchanged. They are

capable of building up from the materials with which they are supplied other genes identical with themselves, so that one cell of the body can grow and divide into two, mother and daughter cells having the same genetical constitution. Mutation is a rare and rather haphazard event, which can be artificially brought about by the use of chemicals which will penetrate the nucleus of the cell without destroying it or by physical agents such as radiation. Apart from such experiments it is not likely to occur spontaneously much more frequently than once in every fifty thousand generations for any one gene. Such a change, when it does occur, will be a chemical one and consist in such an event as a rearrangement of a group of atoms, or the loss of a side-chain from a molecule. Differences so caused may be trifling or critical in their effects.

The genes exert their effects through their control of biochemical reactions, by speeding up some chemical reactions and retarding others, or by inhibiting some reaction until the chemical environment is such as to trigger it off. Their action resembles that of enzymes in that, though involved in chemical changes, they maintain their own identity. They control the development of the individual from the earliest stage of the fertilized ovum up to adult life and into old age. The variation due to some genetic differences may be seen very early, e.g. into a male or female constitution, but in other cases much later; and there is no point in life at which one can say that all latent genetic potentialities must have been manifested.

(As a simple example of a genetic difference we may take the condition known as phenylketonuria which can be attributed to a single abnormal gene. Whereas the normal gene permits of normal body chemistry, the abnormal gene fails to provide an enzyme which converts the amino-acid phenylalanine into tyrosine, a foodstuff of vital importance to the brain.) If the individual has one normal and one abnormal gene, he can still deal with the phenylalanine and can be mentally normal; if he has two abnormal

genes, he cannot carry out the essential chemical processes, and the phenylalanine is excreted in the urine as phenylpyruvic acid and can be identified by a simple colour reaction. The metabolic deficiency prevents normal development of the brain, and the abnormal individual is mentally defective.)

We must think of these genetic-biochemical relationships as being ones of great complexity, involving many stages. H. J. Muller (1956) puts it—

Whatever may be the nature of the primary chemical products of genes within the cell, these products must be of thousands of different kinds, corresponding with the thousands of different genes, and these products must interact with one another in innumerable ways to form secondary products, tertiary products and those ever further removed from the genes. It is usually only after a most intricate web of these inter-actions has been followed through that those end-products are at last found which we become aware of as the characteristics of the organism. . . . Because of the great indirectness of the route connecting the genes with these end results, it is evident that any given characteristic must be a resultant of the action of many genes, some playing a major role in its development but many more playing only a minor role.

Although the genes are transmitted as independent units, we must think of the genetic constitution as also largely acting as a whole. We shall find that the cumulative effects of the minor end results of many genes will be just as important in some fields as the major effects of single genes in other fields.

Once a major gene has produced its distinctive difference, this is not the end of the matter; for the specific abnormality so caused will become involved in a tangled web of secondary and tertiary consequences. Grüneberg (1947) has shown how, in the experimental animal though not in man, such complex problems of causation may be sorted out by tracking back through ever earlier stages in the development of the embryo. In the case of one particular gene in the rat (Fig. 8.2), the abnormality caused is quite simply an anomaly in the development of cartilage; the more distant effects, however, are of an extremely various kind, so that apparently clinically distinct diseases, liable to lead to death in quite different ways, can be traced back to this one cause.

Just as the effects of one gene may be many, so also the converse is true and the same end results can be brought about by different genes. There is a well-known form of blindness which is caused by a disease of the retina of the eye, *retinitis pigmentosa*. This condition can be watched by the oculist, with the aid of the ophthalmoscope, from its very earliest stages; and the actual pathological processes involved can be seen in all their detail. Nevertheless there are several different genes which can bring about this condition; and by an examination of the eye alone

it is impossible to say which of the genes is the one responsible.

The effect of the genes is not limited to early development. Both growth and regression in all stages from the embryonic to senile decay are under genetic control. Many genetically determined conditions—baldness in men, for example—do not usually become

FIG. 8.1. PART OF A MODEL OF A GIANT MOLECULE OF DESOXYRIBONUCLEIC ACID (DNA)

DNA is found in the chromosomes, and (with minor exceptions) only in the chromosomes, of all living cells. A single molecule probably consists of at least a thousand turns of the helix shown above. The section shows how the groups of atoms are arranged in two intertwining spiral chains. Each chain consists of phosphate and sugar groups. Attached to the latter are various chemical "bases" which link one chain with the other. The varying sequence of the bases along the molecule may provide a kind of code by which hereditary characteristics are transmitted from one generation to the next.

(By courtesy of the "Observer," 1956, and Dr. F. H. C. Crick)

manifest until well on in adult life. In many of these the "pedigree of causes" will be more complex than in phenylketonuria, and allow, therefore, greater scope for variability in manifestation. *Diabetes mellitus* is a disease which is often genetically determined. It is due fundamentally to a deficiency of a circulating enzyme, insulin. Fig. 8.3 shows part of the network of consequences which can be set in motion by the failure to secrete sufficient insulin. Some of the end results are due to the impaired ability to burn sugar, others to the efforts of the organism to compensate for this. The course taken by the abnormality is influenced by secondary factors, some of them attributable to other genes, others the products of

non-genetical factors, such as medical treatment, including the administration of insulin.

For an understanding of the way in which a genetical difference may manifest itself in an observable

may, indeed, suppose that the route from the gene to the end result will be more complex and indirect than ever; but we may still be able to show that certain effects can be put down to genetical causes.

"PEDIGREE" OF CAUSES OF LETHAL CARTILAGE ANOMALY IN THE RAT

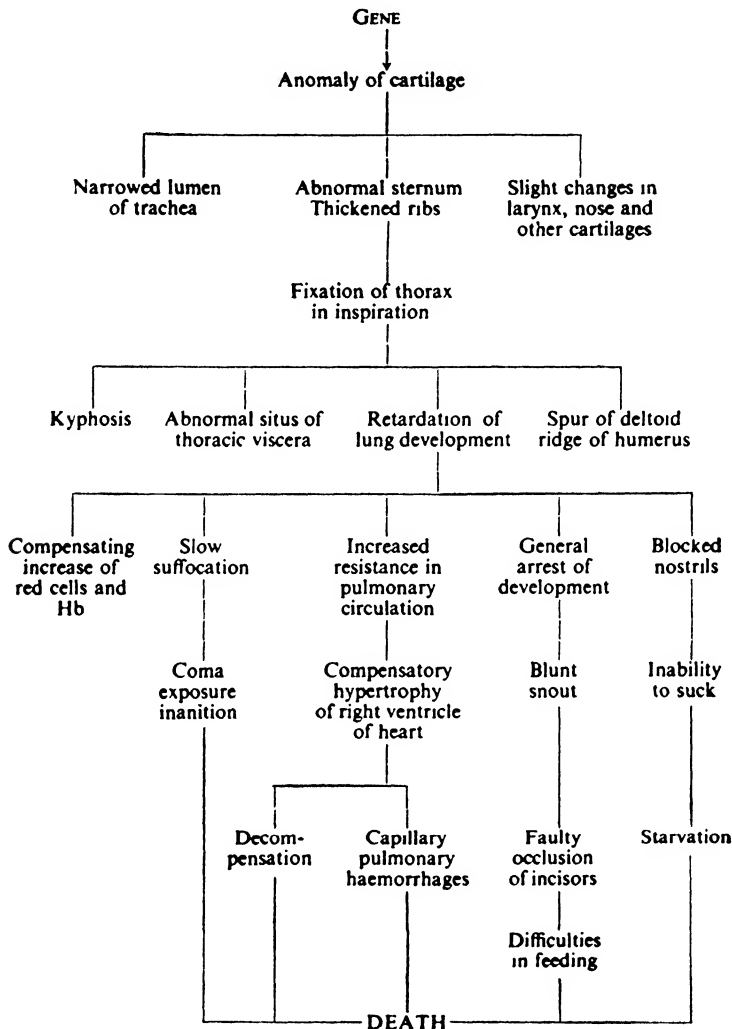

FIG. 8.2. "PEDIGREE" OF CAUSES OF LETHAL CARTILAGE ANOMALY IN THE RAT
(After Gruneberg, 1947, by courtesy of Prof. H. Gruneberg and Messrs. Cassell)

characteristic of the individual we depend on research and knowledge in many fields, such as embryology, biochemistry and physiology. Even in the best studied instances, our knowledge of the dynamic chain will be full of gaps. The application of genetics to the study of abnormal psychology is no different in principle from its applications in biology or medicine. We

though we can claim no detailed knowledge of the hypothetical genes involved or their mode of operation.

From what has been said it can be seen that it is the genes which are inherited, and not abnormalities or diseases themselves. The genes can only act in an environmental framework; and their effects will be

influenced to a greater or lesser degree by the nature of that environment. One of the aims of genetical research is to discover how much of the total variance occurring in a given population can be attributed to genetical and to environmental differences between individuals. To understand how genetical variation can occur, we have to observe the way in which the

either chemically identical with its partner, or differing from it in some small though possibly important way. The genes are arranged along the length of the chromosomes, which are threadlike structures, often condensed in appearance because they are spirally twisted. The order in which the genes are arranged along the chromosome is largely held fixed, so that gene pairs lie

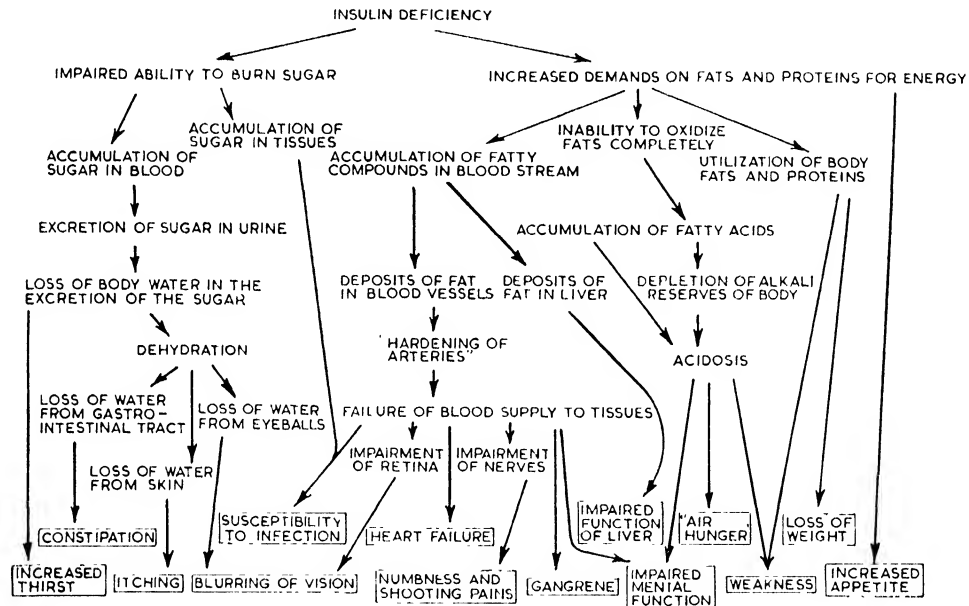

FIG. 8.3. SOME OF THE CONSEQUENCES OF THE RELATIVE DEFICIENCY OF INSULIN WHICH OCCURS IN DIABETES MELLITUS

(From Neel and Schull, 1954, after Anderson, by courtesy of Prof. J. V. Neel and the University of Chicago Press)

genes are distributed in their descent from parent to child.

LOCATION OF THE GENES ON THE CHROMOSOMES

The totality of the genes are organized into chromosomes, which are contained within the nucleus of the cell. Every species of living thing, with the exception of the most primitive, has its own characteristic number of chromosomes, there normally being twenty-three pairs in man (Tjio and Levan, 1956). Every cell in the body has its full complement of chromosomes, except for the sex cells, ova and spermatozoa which contain only half the normal number, one from each pair. The genes are too small to be seen individually—it has been estimated that in man each cell contains between 40,000 and 80,000 genes (Neel and Schull, 1954)—but the human chromosomes can be seen when suitably stained (Fig. 8.4). The chromosomes exist in pairs, each member of which is homologous to the other; the genes of which they consist are also homologous and paired, each member of a pair being

opposite one another in the chromosome pairs. In experimental animals, the gene can be identified both by its position along the length of a particular chromosome, and also by its effects, so that chromosome maps can be drawn. A particular gene can be shown to be capable of taking, in some instances, one of two or more alternative forms; and each of these forms will be likely to have a slightly different effect in development. Thus one of the genes which determines a man's blood group can take one of three forms, A, B and O. This gives the possibility of six different types of constitution—AA, AB, AO, BB, BO, and OO. The serologist can test for the presence or absence of an A or B gene, and so can distinguish some of these blood types from one another; but he has no way of testing for the presence of the O gene, so that some genetic types cannot be absolutely identified by serology alone.

These blood factors are representative of genes which cause no abnormality, and which are individually very common. Most of the severe conditions

which have a simple genetical explanation are due to rare genes, i.e. the gene which is compatible with normality is extremely common, while its alternative form or allele is rare. Genetically man is extremely diverse, perhaps more so than any other species. To take a limited but practical illustration, Bertinshaw *et al.* (1950) tested the bloods of four hundred and seventy-five Londoners with eight groups of antisera, and were able to identify two hundred and ninety-six

FIG. 84. THE HUMAN CHROMOSOMES

(Tjio and Levan, 1956; by courtesy of Dr J. H. Tjio and "Hereditas")

different combinations of blood groups. With the exception of identical twins, each individual is genetically unique. The existence of so much genetical diversity is a good reason to expect a genetical contribution to many modes of variation in which we are interested.

FORMATION OF THE SEX CELLS: FERTILIZATION

In the ordinary process of bodily growth and multiplication of cells, each chromosome builds up a duplicate of itself before the cell divides, so that each daughter-cell contains twenty-three pairs of chromosomes like the mother-cell. When the daughter-cell is to be a sex-cell (ovum or spermatozoon) the chromosomes do not build up duplicates but simply separate, so that the daughter-cell contains twenty-three single chromosomes. When spermatozoon unites with ovum in the process of fertilization the twenty-three pairs are re-established. The new individual therefore comes to have half his chromosomes from his father

and half from his mother; but of the chromosomes he obtained from his father, the proportion derived from his father's father and from his father's mother need not be equal at all. The process of selection within pairs of chromosomes is entirely random. In this way a great deal of mixing up of chromosomes, and therefore of genes, goes on from generation to generation; but the mixing is much more intimate than this method alone would permit. Pairs of chromosomes may exchange parts with one another by a process called crossing-over, so that the pair of chromosomes $A_1B_1C_1D_1$ and $A_2B_2C_2D_2$ may give rise to the new chromosomes $A_1B_1C_2D_2$ and $A_2B_2C_1D_1$. The exchange of genes occurs in whole blocks at a time; and in this way a single chromosome passed from father to child may contain genes from both the two paternal grandparents.

DOMINANT, RECESSIVE AND INTERMEDIATE GENES

In discussing the blood groups it was indicated that the serologist cannot distinguish between individuals of the AA and AO constitution, because both give, equally strongly, the reaction typical of A gene-carriers. If the A gene is present, the O gene appears to have no effect. Under these circumstances A is said to be dominant and O to be recessive. If AA produced a stronger reaction than AO, one could call the A gene intermediate. Not only is A dominant to O, but so also is B, so that the serologist is equally unable to distinguish between BB and BO individuals. However A and B are not dominant or recessive to one another, and the AB individual gives both the A and the B serological reactions.

From knowing what happens in the formation of the sex-cells and at fertilization, we can easily see what the offspring will be when individuals of the various types mate together. O is by far the commonest of the three genes, with A the next, while B is relatively rare. The commonest constitutions are therefore OO and AO. The first, having two genes of the same kind, is said to be homozygous for O, while the second is heterozygous. If an AO man mates with an OO woman, the child will be able to get either an A or an O gene from the father, only an O gene from the mother. The children of such a mating will tend to be AO and OO with an equal frequency. Suppose the dominant gene in which we are interested is not the normal A gene, but a gene which causes some abnormality or defect. Then, as this gene, *D* let us call it, will be rare compared with its normal allele *d*, the great majority of people will be of the *dd* constitution and normal, while there will be some people of the *Dd* constitution and abnormal. The *DD* constitution will be so very rare that it can be neglected (perhaps even incapable of surviving). A mating between normal and abnormal persons will be a mating of

Dd with dd , and half the children can be expected to be Dd and to show the same abnormality while the other half will be dd and normal. In this way the abnormality will appear to go down the generations from parent to child in a simple and direct way.

Let us take the case of two AO parents (Fig. 8.5). As their child could take either an A or an O gene from either parent, he would have one chance in four of being AA, one chance of being AO, one of being OA and one of being OO. One quarter of the expected children would, in fact, be of a different blood type, the O or not-A type, from both of their parents and from the rest of their brothers and sisters. Now let us suppose that the recessive gene, d , in which we are interested is one which causes abnormality, while the dominant gene D is now compatible with normality. Then two heterozygotes, or carriers, of the Dd type, though normal themselves, will have children one quarter of whom can be expected to be dd and abnormal. If such an abnormal person mates it will probably be with a person who is homozygous for the normal gene, of the type DD ; all the children of this mating will be Dd and normal in appearance (though they carry the abnormal gene). In this case the abnormality, being due to a recessive gene, appears out of the blue in a family tree, is not apparently handed on from parent to child, but may easily strike more than one member of a sibship. An understanding of the simple principles enables one to work out the results of any particular mating for oneself.

Intermediate genes, neither dominant nor recessive, will frequently be found in cases where an effect can be shown to greater or lesser degree, instead of in an

FIG. 8.5. TWO PARENTS OF BLOOD-GROUP AO. POSSIBLE CHILDREN AND THEIR RELATIVE FREQUENCIES

all-or-none way. Quantitative genetic variation is almost the rule when we are concerned with normal and not pathological events.

SEX-LINKED INHERITANCE: COLOUR-BLINDNESS

One of the twenty-three pairs of chromosomes is anomalous in that the two members of the pair are not the same size and hence not strictly homologous. These are the sex chromosomes, of which the X-chromosome is of full size, while the Y-chromosome is hardly more than a fragment containing very little genetic material in proportion. In the case of man, it is

the female which is the homogametic sex, having two X-chromosomes, while the male is heterogametic and has one X- and one Y-chromosome. It will be seen that the female can only produce ova of one kind, with one X-chromosome, whereas the man can produce two kinds of spermatozoa, with an X- or with a Y-chromosome, which will in turn, after union with an ovum, produce respectively a female or a male.

As the X-chromosome is so much bigger than the Y-chromosome, the greater part of it in the male has no

FIG. 8.6. POSSIBLE MATINGS AND TYPES OF OFFSPRING IN RECESSIVE SEX-LINKED INHERITANCE

\bar{X} = abnormal sex-linked recessive gene

XX = normal female

XY = normal male

$\bar{X}X$ = carrier female (unaffected)

$\bar{X}Y$ = affected male

$\bar{X}\bar{X}$ = affected female (rare)

matching partner. Any gene, dominant or recessive, on this part of the X-chromosome, will have its full effect in the male, but if recessive will be liable to be suppressed in the female. Conditions so determined tend to show a very characteristic pedigree (Fig. 8.6), with transmission occurring through the female, but manifestation being practically confined to males. An affected male, mating with a normal female, will have nothing but normal children. His sons will have taken a Y-chromosome from him, without the abnormal gene; his daughters will have taken an X-chromosome carrying the abnormal gene, but will also have inherited from their mother a normal X-chromosome, with the normal dominant allele. If one of these heterozygous daughters marries a normal male, as one may readily see, all her daughters will be normal, though some of them will be heterozygous, whereas some of her sons will be abnormal. Those of them who inherit their grandmother's X-chromosome will be normal, those who inherit the grandfather's X-chromosome will get with it an abnormal gene which can now show its effect. For a female to show the abnormality, she must be the daughter of an affected father and a heterozygous mother.

Red-green colour-blindness is a relatively common perceptual anomaly, in which the affected person has difficulty in distinguishing red and green. Its dependence on a recessive sex-linked, or X-borne, gene is

well established. In this country the gene frequency is over one in twenty, so that rather more than five per cent of males are colour-blind, while colour-blind females are rare. Clearly the frequency of the character in the female will be the square of the frequency in the male, i.e. something over one in four hundred. If p is the frequency of the abnormal gene, and q the frequency of the normal allele, then persons homozygous for the abnormal gene will have a frequency of p^2 , persons homozygous for the normal gene a frequency of q^2 , while heterozygotes will have a frequency of $2pq$.

So far theory. According to Stern (1950) the actual figures observed are fairly close to those expected. There is, however, some discrepancy, in the sense that there are rather more "colour-blind" women than there should be theoretically. First, the gene, or genes, involved is not absolutely recessive but can be regarded as weakly intermediate. Some heterozygous women have "poor colour aptitude," which can be mistaken for colour-blindness. Secondly, there are four main subtypes of partial colour-blindness: deuteranopia and protanopia which are dichromatic types, and deuteranomaly and protanomaly which are trichromatic types. Although all four subtypes are inherited in a recessive sex-linked way, two *loci* might be involved, each with the possibility of three alleles—

1. Gene for normal colour vision, which is dominant to the gene for deuteranomaly, which in turn is dominant to the gene for deuteranopia.

2. Gene for normal colour vision, which is dominant to the gene for protanomaly, which in turn is dominant to the gene for protanopia.

Total colour-blindness, or the ability to see no colours, distinguishing only shades of white and grey, is much rarer. It can be genetically determined by a recessive gene on the homologous part of the X- and Y-chromosomes (Haldane, 1936). Such so-called partially sex-linked genes are much less easily recognized as having a connexion with the sex chromosomes.

Sex-linked inheritance contributes little to the total of psychiatric abnormality. It was once suggested that a sex-linked dominant gene played a part in the causation of manic-depressive disorder, because this diagnosis is made more frequently in women than men. Clearly, women with two X-chromosomes would have twice the chance of receiving the gene that a man with one X-chromosome would have. However, it is easily seen that the fathers and mothers of affected females would have equal chances of being gene-carriers, whereas one would expect only the mothers of affected males to be gene-carriers. In fact, no such differential incidence is found, and other explanations

have to be sought, e.g., in the difference between the male and the female constitution in the broad sense.

EXAMPLES OF DOMINANT INHERITANCE

Although it is probable that there are as many single genes of large effect causing psychiatric illness as other conditions such as metabolic disorders and eye disease, it is not surprising that so far very few have been identified. Nevertheless we have one excellent example in *Huntington's chorea*. This disease received its name from the fact that it was first satisfactorily described by an American country doctor of that name, whose father and grandfather, doctors before him in the same district of Long Island, had observed its appearance in generation after generation of certain local families. These families could be traced back to immigrants in a ship which had docked in Boston Bay some centuries before, and who had sailed from Bures in Suffolk.

In persons who carry the gene, nerve cells in the cortex and the basal ganglia of the brain are liable to die off prematurely. The first symptoms are usually shown in middle life, and the mean age of onset is 35. Men and women are equally liable. The characteristic symptoms are spontaneous jerky movements of the head, trunk and limbs, progressive personality changes, and progressive intellectual deterioration to severe dementia and eventual death, perhaps fifteen years after the onset. The personality changes are often the earliest signs of anything being wrong, and include such changes as increased irritability and aggressiveness, slovenliness, unreliability, lack of control and delinquency. Admission to a mental hospital is likely to become necessary in time. The condition is a rare one: Minski and Guttman (1938) found sixteen cases in 23,000 inmates in London mental hospitals. However, for every case in hospital, there may be as many as four at home (Hughes, 1925, dealing with an American rural population). It was recently estimated (Pleydell, 1954) that there may be 2,000 cases in England and Wales and perhaps twice as many persons destined to develop the disease.

As the condition is dominant and rare, affected persons will be heterozygous. They may pass on to their children either the chromosome with the normal gene, or the chromosome with the Huntington gene. One can expect, therefore, that 50 per cent of the children of a Huntington patient will develop the condition in time. Fig. 8.7 shows a pedigree of Huntington's chorea. A gene-carrier, however, may marry and have a family, and die of some other cause before the disease has had time to develop; in such a case, if some of his children develop the disease, the condition will have skipped a generation. Most gene-carriers do, in fact, have their families before they fall ill, so that the gene is not eliminated at all quickly

from the population by the processes of natural selection. This sort of thing is rather the rule with dominant genes; the abnormalities they cause are often late in onset, or not very severe, or very variable in their gravity. Dominant genes which caused early death, before procreation could occur, would extinguish themselves on their appearance; and every new case would be due to a fresh mutation. The genetic nature of the abnormality would then be very difficult to

the ancestors in the family who had had the disease, rather than those who had not. They also thought it possible that subtle differences in muscular co-ordination and control might be found in heterozygotes. Leese, Pond and Shields (1952) studied a family in which it seemed possible that members who later became affected would show a definite type of abnormality in the EEG some years before other signs were detectable.

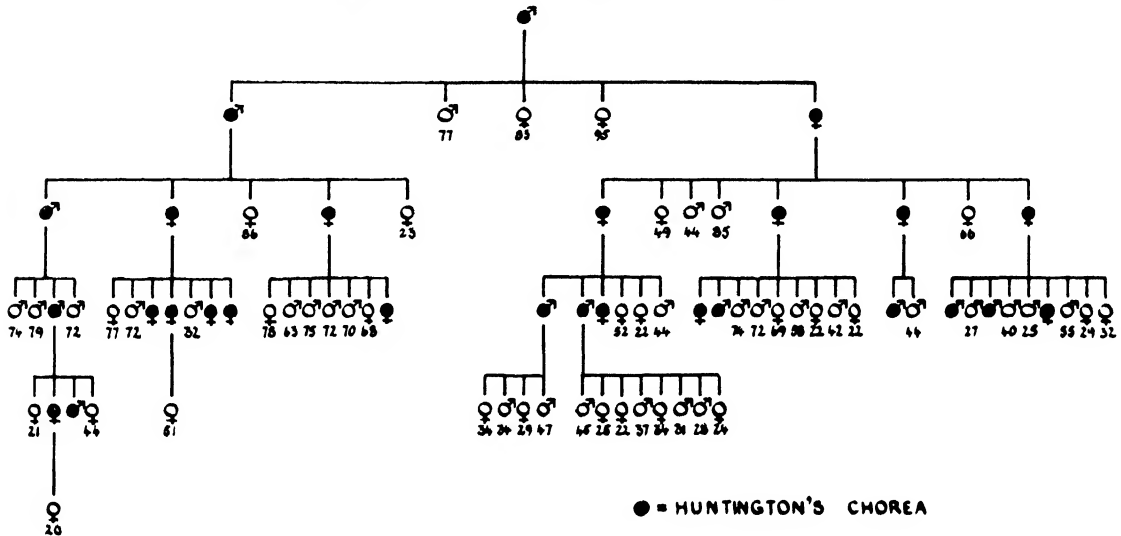

FIG. 8.7. DOMINANT INHERITANCE. FIVE GENERATIONS OF HUNTINGTON'S CHOREA

(After Sjögren 1935)

Extracts from a larger pedigree. None of the offspring of the normal members of the family have had Huntington's chorea. Spouses, all of whom were normal, are not shown, nor are children who died in infancy. The ages given for the unaffected members are those at death or when last heard of. It will be noted that many of the youngest generation still run considerable risk of being affected.

(By courtesy of Prof. T. Sjögren and the "Zeitschrift für menschliche Vererbungs- und Konstitutionslehre")

recognize as all cases would be sporadic. As a general rule, with genes which cause abnormality and disease, there is a balance between mutation on the one hand, causing the perpetual reappearance of the gene in the population, and natural selection on the other hand, removing it by the early death or reduced fertility it causes; gene frequencies tend to remain at an equilibrium.

With a condition of late onset as severe as Huntington's chorea the early detection of genetic carriers becomes important. Not only would this be helpful, especially for the genetic counsellor, in deciding which members of a family were and which were not liable to develop the disease, and to pass on the potentiality to children; but it could also lead to a better understanding of the pathology of the condition. No reliable indications have been found in Huntington's chorea. Minski and Guttmann have suggested that future choreic cases tend to resemble physically

Huntington's chorea can be classified among the presenile dementias. Another example of this group of conditions is *Pick's disease*. This is of rather later onset, and is clinically less well defined and less easily diagnosed; but there is evidence that it too is determined by a dominant gene (Sjögren 1952). Its manifestation rate is not as high as that of the Huntington gene, and modifying genes must play a more important part. Sjögren has calculated that 19 per cent of the parents and 7 per cent of the sibs of patients with Pick's disease were similarly affected, instead of the 50 per cent in each case required by theory. This would mean that the majority of gene-carriers were protected against developing the disease. Sanders (1941), has claimed (with doubtful reliability) that carriers can be detected by means of the Rorschach test some years before the onset of definite symptoms. (Another presenile dementia is *Alzheimer's disease*, pathologically quite distinct from Pick's disease

although clinically often difficult to distinguish. Sjögren thinks that multifactorial inheritance is more likely than dominant inheritance in this case. The pathological changes are identical with those of ordinary senile dementia, though they are occurring unduly early; and the genetical basis may be the presence of a number of genes each favouring to some degree an early senility.

No gene, whose only effect is to cause deterioration and death at an age well after the normal cessation of procreation, will be eliminated from the population by processes of natural selection. It is accordingly probable that the changes of normal senility are primarily gene-determined. However, among the various forms that senile dementia may take, it is quite possible that further specific conditions, like Pick's disease, still remain to be discovered.

Epilota (tuberose sclerosis) is a rare disease, affecting about one in every 30,000 of the general population; it causes multiple benign tumours of the brain, kidney, skin and other tissues and generally mental deficiency and epilepsy. It shows itself in childhood, and as a rule the individual is too abnormal to have the chance of reproduction. Sometimes, however, if the brain is not severely involved, institutional life is not required, and procreation can occur. Nevertheless, because of the restricted fertility the dominant gene which is the cause of the condition is rapidly eliminated from the population, the balance being maintained by fresh mutation; it is estimated that about one case in four is due to a mutation (Gunther and Penrose, 1935).

Of the commoner mental illnesses, the genetic basis of *manic-depressive psychosis* has been regarded as probably unifactorial and dominant (Slater, 1938; Kallman, 1950; Stenstedt, 1952). The gene would ordinarily show itself by causing a tendency to spontaneous variations of mood, probably only in some cases and at some times severe enough to need psychiatric treatment; in fact, the manifestation rate would be more like 30 per cent than 100 per cent, indicating the significance of aetiological factors other than the hypothetical specific gene. The main evidence to support this theory is the high incidence of severe disorders of a similar kind in parents, siblings, and children of manic-depressives. (Table VIII.1.)

Leonhard (1934), has investigated the families of patients with *atypical psychoses*. In many such families there appears to be a dominant form of inheritance, the same atypical features being shown in the mental illnesses of parents and children. Again, in some families schizophrenia appears to be related to a dominant gene of weak and variable manifestation. The schizophrenic illnesses observed by Böök (1953) in an isolated community in the north of Sweden were attributed by him to a gene which

manifested itself fully in the homozygote, but also in 20 per cent of heterozygotes.

Although the genetics of affective and schizophrenic psychoses are obscure, it seems likely that a fair proportion of mental illness may be due to specific dominant genes with low penetrance.

TABLE VIII.1
EXPECTANCY (PER CENT) OF MANIC-DEPRESSIVE DISORDERS AMONG RELATIVES OF MANIC-DEPRESSIVE PROBANDS

(After Stenstedt 1952)

Investigator	Parents	Sibs	Children
Banse (1929) . . .	10.8	18.1	—
Roll and Entres (1936) . .	13.0	—	10.7
Slater (1938) . . .	15.5	—	15.2
Stromgren (1938) . . .	7.5	10.7	—
Sjögren (1948) . . .	7.0	3.6	—
Kallmann (1950) . . .	23.4	23.0	—
		*26.3	—
Stenstedt (1952) . . .	7.4	12.3	9.4

* Dizygotic twins (equivalent genetically to full sibs).

The above risk figures, based largely on Stenstedt, are in most instances calculated after inclusion of some relatives with affective but not certainly manic-depressive disorders. Weinberg's abridged method of age-correction has generally been used. With the use of other methods higher figures would be obtained.

Other psychological abnormalities which have been attributed to dominant inheritance include *specific dyslexia* (congenital word blindness) and *tune deafness*. In the first condition, despite normal intelligence there is a marked difficulty in learning to read and write. Hallgren (1950), found that only twelve out of one hundred and sixteen unselected cases were isolated ones in the family, and that about 50 per cent of siblings having one affected parent were similarly handicapped.

Kalmus (1949), devised a battery of tests which discriminated persons who were unable to recognize commonly known melodies or to sing in tune. The trait showed bimodal distribution, and clear-cut differences were frequently shown between members of the same family, in such a way as to suggest that the variation might be caused by a single dominant gene. Kalmus suggested that the intrusion of such a gene into families of composers like Bach may have contributed to causes which disrupted long-standing musical traditions.

EXAMPLES OF RECESSIVE INHERITANCE

Rather less than 1 per cent of certified mental defectives suffer from *phenylketonuria* (PKU). As has been said earlier in this chapter, this condition is attributable to an inborn metabolic error. Individuals who carry two abnormal PKU genes are entirely

unable to metabolize phenylalanine. These homozygotes are nearly always of very low intelligence, seldom being above imbecile level; and they very rarely propagate. It follows that practically all phenylketonurics will be derived from the mating of two heterozygotes, and in such sibships one in four will be expected to show the trait (cf. Fig. 8.5). Investigations by Fölling (1945), the Norwegian biochemist who discovered the condition in 1934, by Jervis (1939) in the U.S.A. and by Munro (1947) in Great Britain bear this out. In 1953 Jervis analysed all family data then available from these and other investigations. Among two hundred and sixty-six sibships, four hundred and thirty-three persons out of a total of 1,527 were affected, or a little over 28 per cent. When allowance is made by appropriate methods for the fact that only families including at least one affected member are represented, figures closer to the expected 25 per cent are obtained.

In rare recessive conditions like this, one may expect an excess of cousin-marriage in the parents of affected persons. This has occurred in the illustrative pedigree given in Fig. 8.8. If p is the gene frequency, p^2 is the frequency of the homozygote, which may be roughly equated with the observed frequency of the abnormality. It has accordingly been calculated that in the case of PKU $p = 1/245$. The frequency of the heterozygote $= 2p(1 - p) = 1/123$; so we see that heterozygotes may be by no means uncommon even in the case of very rare conditions caused by a recessive gene. If one is a gene-bearer one runs no risk of producing a child with PKU unless one mates with another heterozygote; mating at random the chance of doing this would be $1/123$, but only $1/8$ if one were to mate with a first cousin. Hence it happens that there will be more cousin-marriage among the parents of persons suffering from rare recessive abnormalities than in the general population, and that the rarer the gene the higher the cousin-marriage rate will be. In Munro's series of forty-seven families, the parents were first cousins in five cases (10 per cent), against an expectation of 0.5 per cent for the general population. In the U.S.A. where p is estimated at the higher figure of $1/173$, Jervis found that about 5 per cent of the parents of PKU patients were first cousins.

Unlike pathological dominant genes, recessive genes are quite widely spread in the population, being carried by heterozygotes who suffer no ill-effects; in this way they are protected against elimination by natural selection. Muller (1950) has opined that we all carry somewhere about eight pathogenic recessive genes. Recessive conditions, because of this immunity to selective processes, tend to be graver than dominant abnormalities, of earlier onset and less variable in their manifestations, and possibly also less open to environmental modification of their effects. This

latter quality, however, depends very much on the degree of understanding of their mode of operation. There is evidence to suggest, for instance, that PKU subjects may be partly protected against excessive retardation of intellectual development by controlling their consumption of phenylalanine (Bickel *et al.*, 1953; Blainey and Gulliford, 1956; Woelf *et al.*, 1955).

FIG. 8.8. RECESSIVE INHERITANCE. PART OF A PEDIGREE OF PHENYLKETONURIA
(After Fölling, Mohr and Ruud, 1945)

Note the presence of the defect in collateral branches of the family but not among direct ascendants. In one instance the parents were first cousins.

(By courtesy of Dr. A. Fölling)

It is quite probable that the contribution of rare recessive genes, *in toto*, to the lower grades of mental deficiency is a significant one. This is most likely in the case of patients who show neurological abnormalities in addition to low intelligence. In his survey of all cases of mental deficiency in the Royal Eastern Counties Institution, Colchester, Penrose (1938) classified one hundred and twenty-eight patients as showing disease of the nervous system; of these eight, or 6.2 per cent had consanguineous parents. Even among the non-neurological patients there was an increased consanguinity rate of 3.1 per cent, suggesting that undifferentiated cases of defect include a proportion due to recessive genetic abnormalities. It is interesting that, until the discovery of the characteristic colour reaction in the urine, cases of PKU were indistinguishable from other defectives.

Other recessive conditions in mental deficiency

include *familial amaurotic idiocy*, both of the infantile and of the juvenile type, "true" *microcephaly*, and some cases of spastic paraplegia. These and other conditions are described by Penrose (1954).

Recessive defects are less well-known in the field of the *psychoses*. *Wilson's disease* (Bearn 1953), which is an error of metabolism causing the depositions of copper in the tissues, sometimes causes mental illness; and it is due to a recessive gene. One form of epilepsy, *myoclonic epilepsy* (Lundborg 1903), is due to a recessive; and there is a strong belief that some, at

INTERMEDIATE INHERITANCE

When PKU was first discovered, it was not possible to distinguish between the heterozygote and the normal homozygote, and the gene could be classified as recessive. However, this distinction is now possible (Hsia *et al.*, 1956); if the heterozygote is given a considerable amount of phenylalanine the percentage concentration of this substance in the blood rises to a higher level than in the normal homozygote, and is maintained at a raised level for a much longer time. It would therefore be more

FIG. 8.9. BIMODAL DISTRIBUTION OF PTC TASTE THRESHOLDS IN ENGLISH MALES
(After Barnicot, 1950, by courtesy of Dr. N. A. Barnicot and the "Annals of Human Genetics")

least, of the illnesses called schizophrenic are also recessively determined. The problem of the genetics of schizophrenia is discussed later.

In the field of *sense perception*, recessive genes make their own contribution to the total abnormality in a population. Many cases of deaf-mutism are caused in this way. A study of the offspring of cousins (Shields and Slater, 1956) revealed a relatively high proportion of persons who were blind or partially blind. The inability to taste phenylthiocarbamide (PTC), a substance which most people find distinctly bitter, can hardly be regarded as an abnormality, since about 30 per cent of British and white American people fail to taste the standard solution; but it is an example of a relatively objective and clear-cut variation in perception which behaves as a recessive trait (Snyder 1932). It is not the total inability to taste PTC which is due to a single pair of genes, but rather the taste threshold. When a group of people is tested with a series of solutions of PTC of different strengths, the lowest strength at which they taste a bitter being recorded, the resulting distribution is a bimodal one (Fig. 8.9). Analysis of the family data suggests that those who fall within the non-tasting part of the curve are homozygous for a recessive gene—though the genetics may be more complex than was at first thought, and there is some overlap between tasters and non-tasters.

strictly correct to regard the gene as intermediate between dominance and recessivity. The same can be said if, in the case of a dominant gene, it is found possible to distinguish between the homozygous carrier of two abnormal genes and the heterozygote; in this case dominance would have to be reclassified as incomplete dominance, and the gene be better regarded as intermediate than dominant. Böök, Schut and Reed (1953) have suggested that the gene for recessive microcephaly might express itself in heterozygous form as moderate intellectual impairment, and Penrose (1938) has reported an excess of psychopaths among the relatives of microcephalics. Though microcephaly itself is a rare condition the gene frequency was estimated as between 1/162 and 1/230. Böök *et al.*, conclude that if this is the case borderline intellectual development in 0.5 to 1 per cent of the population might be due to the intermediate expression of the gene for genetic microcephaly. The evidence, however, is scanty so far and other interpretations are possible.

Sometimes it is found that the heterozygote possesses advantages over both types of homozygote. This is the case in the condition known as *sickle-cell anaemia*. The abnormal gene causes the production of a different haemoglobin from that produced by the normal gene. In persons homozygous for the abnormal gene, all the haemoglobin is of the abnormal kind, and the

individual suffers from a severe anaemia and with difficulty survives childhood. The heterozygote has a mixture of normal and abnormal haemoglobins, and suffers only from a slight tendency to get anaemic if circumstances are such as to encourage such a tendency. On the other hand he has a biological advantage in being relatively much more resistant, than persons with only the normal haemoglobin are, to malignant types of malaria (Allison, 1954). Thus it is that in, for example, certain parts of Africa where malaria is common, the gene for the sickle-cell trait (as it is called in the heterozygote) is common too, despite its disastrous effects in the homozygote.

There is no certain case of intermediate inheritance in the field of psychological abnormality. Nevertheless it is possible that one or more of the genes involved in the causation of schizophrenia may be of this kind. It is often held that, if a recessive gene causes schizophrenia in the homozygote, in the heterozygote it may cause only a slight deviation of personality—the “schizoid” personality (Kallmann, 1938). If schizoid persons are, as it is often thought, cool, reserved, self-sufficient, then one can imagine circumstances in which they might have a considerable biological advantage over others. The high frequency of schizophrenia and of schizoid personality which Böök (1953) found in his north Swedish population could be regarded as related to the advantage conferred by schizoid traits in such a remote and hostile environment, in which opportunities for social life are reduced to a minimum. This idea approaches very near indeed to pure speculation. Nevertheless it bears thinking of when we try to explain why schizophrenia, which is biologically so disadvantageous, should also be so common.

PRINCIPLES OF POLYGENIC INHERITANCE

So far, largely for reasons of simplicity of exposition, we have dealt with conditions which are due to single pairs of genes. We now turn to multifactorial or polygenic inheritance.

The genes we have discussed so far show themselves by causing some single massive difference, by which they are, so to speak, labelled. But their effects do not end there. For instance, there is a recessive gene which in double dose causes the carrier to be an albino. But albinos differ from normal individuals not only in being unable to produce normal pigments in the hair, the skin and elsewhere, but also in being, on the average, smaller in stature, less fertile, less intelligent and shorter lived than others. There is no doubt that such fundamental biological variables as size, vitality and fertility are influenced, to some degree, by very great numbers of genes; these variables then show quantitative variation, and one is likely to find curves of distribution of the “normal” or Gaussian

kind, as is the case for instance with intelligence on the Binet scale. It is probable that the great majority of the genes which influence such graded characters do not have any single massive effect of their own; and to them the name of genes of small effect, or polygenes, is given. They are subject to the same laws of segregation as all other genes; but the description of the effects of segregation will be different. Thus Mendel bred races of tall and short peas, the difference depending on a single gene, and got tall and short progeny. In mankind, matings of tall and short parents will have a tendency to produce children of intermediate size, while two parents both of middle height are quite capable of producing both tall and short children. When we leave pathology for normal physiology and psychology, most of the characteristics in which we are interested are of a quantitatively variable kind, and, in so far as they are subject to genetical influence, regulated by multifactorial and not unifactorial inheritance.

Let us suppose that a particular characteristic, say that of height, is determined by three gene pairs, A and a, B and b, C and c. We will suppose that the capital letters tend to cause tallness, the lower-case letters shortness, that there is neither dominance nor recessivity, that all genes are equally common, and that mating is taking place at random. Then the tallest individual we can find, with the constitution AABBCC, will be relatively uncommon; for every one of him there will be six individuals one degree less tall: aABBCC, AaBBCC, AAbBCC, AABbCC, AABBCc, AABBCc. There will be fifteen combinations of four capitals with two lower-case letters, and in fact the population, graded by height, will be distributed according to the terms of the expansion of $(\frac{1}{2} + \frac{1}{2})^6 = (1 + 6 + 15 + 20 + 15 + 6 + 1)/64$. It is readily seen that the commonest group will be the middle group, with average height. It will also be seen that if we generalize, and write the expansion of $(p + q)^n$, in which $p + q = 1$, as n gets bigger and bigger we get a closer and closer approximation to the normal curve, which is skewed over the middle part of the curve very little, when n is big, even if p is bigger than q .

We may, in fact, say that where we find distributions of a normal kind we shall think of multifactorial inheritance, but not in cases where the distribution is not normal. The ability to taste PTC is, indeed, a graded character; but its distribution (Fig. 8.9) is not normal but bimodal with relatively little overlap in the middle part of the curve. Multifactorial inheritance will not do, therefore, in that case. However, even if the distribution is normal, this is no proof of a genetic and polygenic determination. A multiplicity of environmental or non-genetical factors, capable of operating additively, could conceivably result in the

same sort of distribution; and a combination of polygenic and environmental factors could very easily do so. The proof of a genetical basis will depend on other observations.

Such a further observation, which may be made with a character showing normal distribution, is the demonstration of a regression equation linking the deviation from average values shown by a series of subjects with the deviation shown by their relatives.

FIG. 8.10. DISTRIBUTION OF INTELLIGENCE

Estimate based on Binet test of three hundred and one defective and two hundred and sixty-one normal children. Jaederholm's data, from Pearson, 1931. Scores are shown in terms of standard deviations.

(By courtesy of "Annals of Human Genetics")

As an example, we may take the case of intelligence. As is well known, the Binet I.Q. is normally distributed, with mean at 100 and with a standard deviation of about 16 points. If we measure the intelligence of a series of schoolchildren, and also those of their sibs, it will be found that the correlated data are fairly well described by a linear equation: the I.Q. of the sib will tend to deviate from the mean in the same direction as that of the original subject or proband, though not so far. Similar regression equations will link I.Q.s of children with those of their parents, or those of parents with their children. In each case the "regression" is towards the mean. If we put the data in the form of correlation coefficients, they are of the order $+0.5$ or rather more. This corresponds rather exactly with expectation on the genetical hypothesis, which involves the fact that pairs of sibs, or parent-child pairs, will have half their genetical equipment in common. Such a finding is very difficult indeed to explain on any environmental causation. The strength of the argument is to some extent reduced by the fact

that, in fact, people do not mate at random but preferentially with others of like intelligence to their own, and that there is a high positive correlation coefficient between the I.Q.s of spouses (as also of betrothed couples, and even friends). The existence of this homogamy would cause by itself some degree of positive correlation between sibs, but not enough to explain all that is found (Cattell and Willson, 1938; Conrad and Jones, 1940; Outhit, 1933; Fraser Roberts, 1940; Thorndike, 1944).

One need not be restricted to the closer blood relationships. A correlation coefficient of $+0.25$ would be expected between probands and their grandparents, grandchildren, uncles, aunts, nephews and nieces; for first cousins the correlation should be $+0.125$. These were in fact the order of the resemblances found between relatives in various physical measurements by Karl Pearson and the biometricians in the early years of the century, and were thought by them to be a disproof of Mendelism. The interpretation of the findings, on a Mendelian basis in terms of multifactorial inheritance, had to wait until the work of Fisher (1918) on stature. It was twenty years after that before the concept of polygenic inheritance was applied to intelligence, although its normal distribution was known.

LOW INTELLIGENCE

As long ago as 1912 Jaederholm made a survey of the intelligence of the great majority of all children in Sweden who were excluded from the ordinary schools on account of mental deficiency, together with a sample of normal schoolchildren. He used a modification of the Binet test. The results were analysed by Karl Pearson (1914). He showed that the distribution of scores corresponded reasonably well with the normal curve. The fit was three times better if the defective group was included along with the normal group. Not more than one-third of the defective group fell outside it, and there was a good deal of overlap between the scores of the brighter of the so-called defective children and those of the duller children attending the ordinary schools. Fig. 8.10, taken from a later publication of Pearson (1931), shows this clearly. Later studies have given similar results. Thus Roberts, Norman and Griffiths (1935) made a survey during the 1930s of all children of school age in the city of Bath. Table VIII.2 shows part of the frequency curve of Stanford Binet I.Q.s which shows that about down to I.Q. 45 there is no excess of children with low scores. Below that level there was an excess of idiots and imbeciles.

Roberts (1950, 1952) made a special study of the siblings of the 8 per cent of the children with the lowest I.Q.s. Their mean score was 77.4, that of their sibs 88.1, and the regression coefficient was 0.53. At the other end of the scale, Terman's (1947)

TABLE VIII.2
NORMALITY OF LOWER PART OF THE FREQUENCY CURVE OF STANFORD-BINET I.Q.s

(Based on a complete sample of 3,361 children)

(From Fraser Roberts, 1952)

Range of I.Q.	Expected No.	Observed No.
<i>Above 73.78</i>	3,193.0	3,195.2
73.78 — 67.57 . . .	100.8	94.9
67.57 — 44.97 . . .	66.5	58.4
<i>Below 44.97</i>	0.7	12.5

"superior children," with I.Q.s over 140, had offspring with mean I.Q. of 128. As has been said, these regressions are expected on the basis of polygenic inheritance, and are not compatible with single factor inheritance. However, when we come to persons of extremely low intelligence, idiots and imbeciles with I.Q. of 45 or less, comparable regressions are no longer observed. On Robert's small series, the I.Q.s of sibs of the imbeciles ranged from 88 to 117 with a mean of 99.9. This suggests that the occurrence of such grave defects is not accounted for by normal variation and polygenic inheritance, a conclusion which also follows from the fact that the curve of distribution deviates from normality at its negative extreme. What is suggested is the operation of special factors, such as injury, disease and, if genetical in nature, single dominant or recessive genes. A small part may also be played by incompatibilities of blood group between mother and unborn child such as may occur with respect to the Rhesus factor, or chromosomal anomalies as is now suspected in Mongolism. However, this whole class is not a numerous one, and not to be compared, as a social problem, with the very much larger numbers of the feeble-minded.

PERSONALITY AS A GRADED CHARACTER

The genetical background of intellectual abnormality can thus be regarded as determined polygenically for the greater part. The same is probably largely true on general grounds for the genetical background of personality abnormality. The situation, however, is more complex than in the case of intelligence. Personality is more difficult to assess or measure, it is a much less unitary character than intelligence and its manifestation throughout life is subject to quite wide fluctuations depending on a variety of circumstances. However, it is generally found helpful to regard personality traits as graded characters, and the same is true of major factors in personality, such as extraversion and neuroticism. When a group of persons is rated or measured on any personality scale it is generally found that, as in the case of intelligence, the scores tend to fall into the shape of the normal dis-

tribution curve. In so far as this distribution is reliable and is genetically determined it is likely to be due to the combined influence of many genes. In our opinion, that is certainly a likely hypothesis in the cases of neuroticism and extraversion, as described in this book, though there are certain points that will need clarification. Thus Eysenck finds it profitable to see the factor of neuroticism, as a psychological measure, as unitary in nature. The psychiatric geneticist would think rather of a predisposition determined by polygenic factors of somewhat heterogeneous kinds, though their effects, measured along a single dimension, could well fit in with Eysenck's findings.

In the psychotic dimension, matters are different again. A continuously graded factor of psychoticism would not account, by itself, for the specificities of inheritance in schizophrenic and manic-depressive families; but it might describe the non-specific variation in the susceptibility to these illnesses. Hypothetical specific schizophrenic and manic-depressive genes must both be supposed to have reduced rates of manifestation, and whether they are manifested or not could well depend on the intensity of a "psychoticism" factor. Such a conception would have consequences which could be tested by appropriate investigations.

Methods and Aims of Genetical Analysis

It is now the place to give an account of the research methods which may be used in psychiatric genetics, including those which help us to understand the mode of inheritance, such as family and population studies, and those which help to distinguish between the effects of heredity and environment, such as the study of foster-children and twins. A beginning must be made with work on animal behaviour.

ANIMAL STUDIES

Although human beings are in some ways very favourable subjects for genetical study, there are ways in which they present particular difficulties. One cannot plan human breeding experiments; the size of the human family is small; and there is a time interval of some thirty years between one generation and the next. There are, therefore, advantages in pursuing psychological studies on laboratory-bred mammals such as rats and mice. This field of work has been dignified by the title of "psychogenetics."

A suitable technique is to select some characteristic of behaviour in which individual differences are shown and can, preferably, be measured. High scorers and low scorers are then separated and inbred with a view to producing distinct strains. If this is successful members of the two strains may then be cross-mated, and the capacities of their offspring measured. If genetical factors play a part, the two strains, with very

different patterns of behaviour, can be built up; and the result of cross-mating is to reproduce individuals of intermediate performance.

Calvin S. Hall (1951), one of the leading American investigators in this field, has summarized the work that has been done on selective breeding up till 1951. His review shows that heredity is an important factor, not only in variations in maze-learning ability, but also in the choice of hypothesis (visual and spatial) adopted in maze-learning, in the preference for a high or low cage temperature, in the amount of voluntary activity displayed, in the speed of reaction, in wildness or tameness, in aggressivity, in emotionality, and in susceptibility to audiogenic seizures, which occur in some rats when the experimenter jingles a bunch of keys. This last trait was found to be inherited as a dominant in one strain and as a recessive in another.

In studies of aggression, black mice have been found to be more aggressive than albinos. One investigator (Ginsburg, 1942) tested the hypothesis that this difference might be caused by early environment, in that the mice might learn their behaviour from cues presented by their mother at an age when they were particularly susceptible. He did this by having some of his black mice reared by albinos, and some of his albino mice reared by black mothers. However, the young ones resembled their biological mothers, and not their foster-mothers or foster-sibs, in aggressiveness. This experiment supported the hypothesis that there are innate differences in aggressiveness in mice.

In a study of Hall's own (1951), emotionality was measured by the extent to which rats tended to defaecate or urinate when placed in a strange environment. Rats scoring high, on this definition, were bred together, as were the low-scorers. The emotional strain became increasingly emotional up to the ninth generation. Selection for non-emotionality yielded less systematic results, though the maximum effect was obtained in a single generation. When the emotional and non-emotional strains were eventually crossed, the offspring had a mean score and S.D. close to that of the heterogeneous parent population, from which they had been bred, but with an excess of low-scorers. Hall inferred that non-emotionality is dominant over emotionality. The emotional rats had significantly heavier thyroids (both sexes), adrenals (males only) and pituitary glands (females only).

Broadhurst (1956), working in the animal laboratory at Bethlem Royal Hospital, repeated parts of Hall's investigation, using more refined methods including brother-sister matings. He too was able to breed emotional and non-emotional strains from an originally mixed population. A cross-fostering experiment showed that maternal influence had no significant effect. There is thus strong evidence that emotionality in the rat, as measured by defaecation under stress, is

under genetical control. Broadhurst has so far found it easier to select for non-emotionality than for emotionality. He has not investigated the mode of inheritance, but has gone on to use his pure strains to study the effect of emotionality on drive. The mode of investigation shows the value of making genetics the servant of psychology.

Hall looks forward to the time when the science of psychogenetics will make a real contribution towards our understanding of the *modus operandi* of the genes and of the environmental modifiability of innate behaviour patterns. "An understanding of psychogenetics," he concludes, "is a prerequisite of a dynamic psychology." A very similar viewpoint is adopted by Williams and his collaborators (1949). They and Mardones *et al.*, (1953) have succeeded in breeding strains of rats which are, and are not, liable to alcoholic addiction; on the basis of this work Williams develops the concept of genetotrophic diseases, in which the genetical deviation is merely the starting point of a chain of effects, into which environmental factors, such as nutritional ones, also enter.

PROBLEMS OF HUMAN GENETICS

The peculiar difficulties of genetical investigations in man have led to the elaboration of special techniques, particularly in the development and refinement of statistical methods. In the hands of mathematical geneticists, such as Sir Ronald Fisher, these have been brought to a level of power and refinement in advance of the observational knowledge to which only they can be applied. Special adjustments have to be made, in the analysis of data, for the fact that the likelihood of making some observations on an individual is affected by the age he has reached, for the fact that nearly all simple and practical methods of selection involve some kind of bias, and for other sources of error, some of which will emerge in what follows.

In genetical investigations on human families, much of the information required is likely to concern people who are dead or otherwise inaccessible, or who have little motive to co-operate. The readiness of contacts to provide information is affected by the theme of the investigation and by the climate of opinion. Owing to an increased liberality of opinion, such investigations in psychiatry are now a good deal easier than they used to be; but it is much easier to carry out research into pairs of twins than, say, into the children of parents both of whom have been mentally ill. It is, as a rule, easy to make a good contact with twins, owing to the fact that the public at large regards twinship as a matter of fascinating interest; it is easier to persuade a pair of twins to come to a psychological laboratory than a complete family.

Where medical records are involved, insurmountable

obstacles may arise, especially when members of a past generation are inquired about. Old, and sometimes even current, records from mental hospitals may be bare in the extreme, and insufficient for a reliable diagnosis. As has been said, sampling nearly always gives rise to problems. The investigator may have to make a choice between the carefully conducted personal study of a small group, with a possible sampling bias, and an unselected series which will include cases about which there is inadequate information. It is nearly always useless, at any rate in this country, to take investigation further than first-degree relatives; but even within this limited family group the obtaining of adequate information about personality and psychological abnormality will be very time-consuming. Parents cannot be equated with sibs or children, for not only do they belong to an earlier generation, but also they have been selected for health by the fact of having attained parenthood.

In studying the genetics of mental abnormality, psychological tests, desirable though they are on theoretical grounds, are often of no great value. Mental illnesses, both neurotic and psychotic, take a fluctuating course, and the state at any one time may be but a poor guide to the nature of a deviation which is best seen over a whole lifetime.

Psychiatric diagnoses, though extremely important for genetical studies, contain unfortunately a large subjective element; the very standards on which they are based vary to some extent from school to school. Efforts, not very successful ones, have been made to get away from diagnosis to single symptoms, to avoid this source of confusion or disagreement. A rather better method of by-passing the subjectivity of diagnosis was used by Leonhard and Schulz in an investigation into the families of schizophrenics: Leonhard diagnosed and classified the probands, and Schulz (1940) carried out the family investigations, each without any knowledge of the judgements of the other.

FAMILY INVESTIGATION

Pedigree Studies

The first attempts to study human heredity were by means of the inspection of single family histories that happened to catch the interest of the physician. In this form the family method was open to some rather obvious objections. Families that are obtained in this way are likely to be the unusual and heavily loaded ones; selected on account of their curiosity value, they are highly unrepresentative and tend to give an exaggerated view of the frequency with which abnormalities occur in the families of affected persons. However, when carried out systematically, on representative material and perhaps in combination with other

methods, family studies remain the basic tool of the genetical research worker. They can take various forms and have various aims, as the following pages will show.

Empirische Erbprognose

By investigating all the parents, siblings and sometimes other more remote relatives of a complete and representative series of patients with a given clear-cut diagnosis one can obtain a reliable idea of what the facts are concerning the family incidence of the same and similar disorders. In some conditions—mostly rare ones—inspection or analysis of the pedigrees obtained in this way will reveal a simple mode of Mendelian inheritance. This was the case, as we have seen, with Huntington's chorea and phenylketonuria. With the commoner psychiatric abnormalities, such as schizophrenia, hereditary mechanisms are likely to be more complex and environmental factors to play a greater part. For these conditions family studies of the type described are nevertheless useful, even though the genetics of the condition may not be clear-cut. Empirical risk figures can be calculated which show the chances of different degrees of relative being similarly affected. The method, known as *empirische Erbprognose*, was first developed by the school of Rüdin in Munich during the 1920s and it has been used fairly extensively so far as the psychoses are concerned, in Germany, Scandinavia and other parts of the world. Not only do the results of adequately planned investigations of this kind often give valuable information on the probable mode of inheritance and the degree to which those persons who are presumed to be carrying the abnormal gene or genes responsible are likely to manifest the psychosis in question; but also the empirical risk figures are of particular value in estimating the genetic prognosis for other members of the family and their potential offspring. Thus the chance of a child of an epileptic developing epilepsy is about 5 per cent, the chance of the child of a manic-depressive developing a recognizable manic-depressive state is about 15 per cent, and the risk for the child of a schizophrenic has been estimated at figures from 9 per cent for some forms of the illness to 20 per cent for others. Estimates have similarly been obtained for siblings, nephews and nieces, and grandchildren in these and other clinical groupings. In recent years in the United States and elsewhere a number of heredity counselling clinics (Reed, 1955) have grown up, which rely heavily on the results of family investigations of this kind. The risks for relatives must of course be compared with those for the population in general, which are higher than might have been thought.

Because of the particular value of twins to genetical research, Kallmann (1953) in the United States has

combined the twin and family methods, starting with a large series of patients who happened to be twins, and investigating their co-twins and other relatives. Table VIII.3 gives his principal findings in the case of

TABLE VIII.3
RISK OF SCHIZOPHRENIA FOR RELATIVES OF
SCHIZOPHRENICS

(After Kallmann, 1946, 1950)

Class	Percentage risk of schizophrenia
Children of two non-schizophrenic parents (general population)	0.9
Relatives of adult schizophrenic index cases—	
Not consanguineous	
Step-sibs	1.8
Spouse	2.1
First cousins	2.6
Nephews and nieces	3.9
Grandchildren	4.3
Half-sibs	7.1
Parents	9.2
Full-sibs	14.2
Dizygotic co-twins	14.5
Dizygotic co-twins of same sex	17.6
Children with one schizophrenic parent	16.4
Children with two schizophrenic parents	68.1
Monozygotic co-twins	86.2
Monozygotic co-twins living apart for at least five years	77.6
Monozygotic co-twins not so separated	91.5

schizophrenia. It will be seen that the expectation of schizophrenia increases with closeness of blood-relationship to the proband, rather than with environmental similarity, though the latter has some effect, as is shown in the figures for step-sibs and for identical twins living together or apart.

Although in practice most family investigations of abnormalities start from hospital populations, others originate in surveys of schoolchildren or army conscripts. In some studies it has been possible to ascertain all cases of a specific abnormality in a defined area, and to start family investigations from there.

Among the earliest positive results of systematic family research was the elimination of some old and hoary misconceptions, such as the theory of anticipation. According to this, familial disorders tended to occur earlier and earlier in life in succeeding generations, until, mental deficiency taking the place of mental disorder, the morbid strain was eliminated. This has been shown to be a statistical artefact, caused by the fact that the most accessible information in a family study will be about the later disorders of the older generations, and the earlier disorders of the

younger generations. With this exploded theory went also the idea that the defectiveness of a human strain might show itself indifferently in a great number of forms, schizophrenia, epilepsy, psychopathy, criminality, prostitution, vagrancy, mental defect, etc., all arising from a single genetical cause. *Empirische Erbprognose* taught the lesson that different forms of psychiatric abnormality must be distinguished; and thereby it has become one of the foundation stones on which a scientific diagnostic classification will have to be based.

Genetical Analysis and Psychiatric Classification

It is a fashionable tendency in psychiatry to consider that there is no real difference between the "psychoses" and "neuroses," both these words being mere terms of convenience. This view is not supported by the results of family investigations. Such studies, in the hands of many workers, consistently confirm the existence of a real difference between conditions like schizophrenia or manic-depressive disorder, on the one side, and anxiety states, hysteria, etc., on the other. The difference between these two classes of conditions is not one of gravity but of specificity. Thus investigations of the relatives of schizophrenics have shown that they are more than normally liable to schizophrenia, but have no excessive risk of becoming manic-depressive or epileptic. On the neurotic side, the relatives of anxiety neurotics are more than normally liable to anxiety neurosis, but also are more than normally liable to hysterical illnesses, reactive depressions, and other neuroses (Brown, 1942). On the genetical hypothesis we are able to account for this class difference by supposing that in the aetiology of schizophrenia and manic-depressive disorder single genes of large specific effect are involved, whereas in the aetiology of anxiety states and hysteria, any genetical factors involved are probably polygenic and not very specific in their effects. This fits in well with the observation that neurotic modes of behaviour are within the compass of all of us, and can be regarded as non-pathological, whereas schizophrenic behaviour is beyond the normal range. If large numbers of individuals are subjected to physiological and psychological stress, such as occurs in war-time, the incidence of neuroses increases *pari passu* with the increase of stress, while the incidence of schizophrenia remains practically constant.

As a matter of historical fact, the classification most frequently used in genetical investigations in psychiatry has been derived from Kraepelin. This does not mean that psychiatric genetics is permanently wedded to it. Great improvements can be expected, and genetics can be expected to make its contribution. Kraepelin regarded the condition he called "paranoia" as being a syndrome in its own right; but his pupil Kolle (1931),

who investigated the families of the patients whom Kraepelin himself had diagnosed as cases of paranoia, found that, from the familial genetical point of view, they did not distinguish themselves from paranoid schizophrenics. This investigation gave the death-blow to paranoia as a specific disease, and thereby solved a problem of classification which was beyond the reach of the unaided clinician.

Offspring of Two Psychotic Parents

By investigating the children of particular matings, light may be thrown both on the mode of inheritance of a predisposition and on its genetical homogeneity. An excellent example of what may be done in this way is provided by the work of Elsässer (1952). He collected, from his own material and from the work of others, one hundred and thirty-four pairs of husbands and wives, both of whom had suffered from an endogenous psychosis. Most of these were either typical cases of schizophrenia or fairly typical manic-depressives, but as many as 29 per cent were sufficiently atypical, not to be readily classified in either of the two main diagnostic groups; they included paranoid involuntal psychoses, confusional psychoses, etc., and Elsässer thinks that there were so many of them because psychotic parents are not a random selection

of psychotic patients in general. There were four hundred and twenty-four children who passed the age of sixteen from these unions, and of these eighty-eight certainly and twenty-three probably had had psychotic illnesses by the time of the investigation. In his calculations Elsässer counts each of the doubtful cases as a half. Of course, a considerable part of the total number of children observed had lived through only a fraction of the life-span during which they would be liable to an endogenous psychosis (approximately fourteen to forty-five in the case of schizophrenia). When allowance is made for this, Elsässer could say that he had observed three hundred and twenty-nine life-expectancies for schizophrenia, two hundred and five for manic-depressive psychosis. Set against these denominators, the risks these children faced of developing schizophrenia or manic-depressive illness were two to three times as great as those facing children of one psychotic and one normal parent. This fact alone fits well with a genetical hypothesis of causation.

As will be seen from Table VIII.4, Elsässer calculated risks separately for the different combinations of psychotic parents. There were thirty-four families where both parents were schizophrenic; they produced twenty certain and eight probable schizophrenics

TABLE VIII.4
THE CHILDREN OF TWO PSYCHOTIC PARENTS

Data of Elsässer, Schulz and Kahn
(After Elsässer, 1952)

Number of Parental pairs	Parental mating	Number of children over 16	Non-psychotic children			Psychotic children (doubtful cases shown as $\frac{1}{2}$)					Corrected risk for endogenous psychosis (per cent)
			Normal	With psychiatric abnormality (mostly minor) or uncertain information*	Total	Schizophrenia	Manic-depressive psychosis	Atypical psychosis	Endogenous psychosis, ? nature	Total persons	
34	Schizophrenia x Schizophrenia	96	38	30	68	20 $\frac{1}{2}$	—	—	—	28	39.2
20	Manic-dep. x Manic-dep.	47	28	5	33	1	9 $\frac{1}{2}$	2	1	14	44.4
19	Schizophrenia x Manic-dep.	68	35	14	49	6 $\frac{1}{2}$	6 $\frac{1}{2}$	1	2	19	31.2
23	Atypical x Schizophrenia	91	53	23	76	8	1 $\frac{1}{2}$	3	$\frac{1}{2}$	15	21.3
21	Atypical x Manic-dep.	55	32	12	44	—	4 $\frac{1}{2}$	4 $\frac{1}{2}$	—	11	28.8
17	Atypical x Atypical	67	27	16	43	5	5 $\frac{1}{2}$	10 $\frac{1}{2}$	$\frac{1}{2}$	24	41.3
134		424	213	100	313	88 certain + 23 doubtful = 111					

* The hundred persons in this column consist of sixty-eight who are described as *mässig auffällig* (moderately conspicuous), fifteen psychopaths, ten persons with mental defect or neurological disease and seven about whom there was insufficient information.

in a corrected total of 61.3, equivalent to a percentage of 39.2. Not one of the children was manic-depressive. There were only twenty unions where both parents were manic-depressive; they produced nine certain and one probable manic-depressive children, and four other psychotics. One of these last, the daughter of two manic-depressives with not quite typical illnesses beginning in each case after the age of fifty, was a schizophrenic. The risk for psychosis was 44.4 per cent. The offspring of matings of schizophrenics with manic-depressives produced equal numbers of both major psychoses; the risk for psychosis was 31.2 per cent. The matings in which one or both parents had an atypical psychosis also resulted in a risk for the offspring of about the same magnitude. While analysis suggested that these atypical psychoses in the parents were in some instances, genetically, schizophrenic or manic-depressive, it also indicated that in others they were breeding true and appeared to be genetical entities in their own right. This is in keeping with the findings of Leonhard, which have been mentioned earlier.

It seems clear from these results that, if there is a genetical relationship between schizophrenia and manic-depressive psychosis, it cannot be a close one. It is interesting also that the illnesses of the children were not of any exceptional severity; if a child received two abnormal dominant genes, one from each parent, he might well show something of that kind, or perhaps a lethal or semilethal condition. There was one child of two schizophrenics who was born with supernumerary fingers and toes and died when a few days old—but this was probably coincidental.

Probably the most important finding is that not more than 40 per cent of the children of two schizophrenics were similarly affected, and that only some 16 per cent of their non-psychotic sibs could be described as schizoid personalities. If all schizophrenic illnesses depended on a single recessive gene, then all the children of two schizophrenics would themselves be homozygotes, and accordingly liable to the disease. On this theory, the fall from the expected 100 per cent to 40 per cent is difficult to explain; it becomes easier to suppose either that schizophrenia is heterogeneous, and that a variety of different specific genes are responsible from case to case, or that dominant inheritance with diminished penetrance plays a role. It is interesting, however, that in the only family where both parents had a deteriorating schizophrenia of hebephrenic or catatonic type with early onset, five out of the six children who survived infancy were schizophrenic and the sixth was an odd personality. It would seem likely that in this family, at least, parents and children were all homozygous for the same gene. This family was not used in Elsässer's statistics as, unlike the other families, it had

been selected through knowledge of the abnormal children.

Another highly important point is that of the non-psychotic children of these marriages 70 per cent were completely normal and only 5 per cent were regarded by Elsässer as psychopathic. On this ground any attempt to explain the high incidence of psychosis in the children as the result of the psychological effects of being brought up by a pair of psychotic or psychotic-to-be parents becomes very unconvincing; if the environment was as pathogenic as that, how were these normal children so completely spared?

Offspring of Consanguineous Matings

As we have seen in an earlier discussion, the heterozygous carrier of a rare recessive gene is much more likely to mate with another heterozygote if he marries a blood relative, such as a cousin, than if he marries at random. If he does, he will greatly increase his chances of producing a homozygous and abnormal child. The present authors, with their colleague W. L. B. Nixon (1957), investigated a series of three hundred and fifty-five mental hospital patients who were notified as the children of related parents, and compared them with a control series of equal size. There were significantly more schizophrenics in the proband than in the control series, ninety against sixty-three, the distribution of other diagnoses showing no significant difference. The existence of a so much higher incidence in the one series than in the other is what would be expected on the hypothesis of a recessive gene, but on this hypothesis alone one would have expected a greater difference. Taking into account the figures obtained, the best estimates available of the frequency of cousin marriage and the frequency of schizophrenia, the authors calculate that not more than one-sixth of the totality of schizophrenia could be attributed to a recessive gene. This is of course a provisional view, and would have to be modified if later workers found different incidences.

Linkage

If two genes are carried on the same chromosome, they are said to be linked, and the way in which each is handed on from parent to child will not be independent. Let us suppose that *X* has both the gene for Huntington's chorea and also the dominant gene for polydactyly, and that these two genes are linked. Now if *X* got both these genes from one parent, they will have come to him on the same chromosome, and any child he has will be liable to get from him either both of them or both of their normal alleles. If, however, *X* got one gene from his mother and the other from his father, then they will be on opposite members of the chromosome pair, and his children will be liable to get one or the other, but not both or neither. There

is a certain amount of recombination of parts of chromosomes by "crossing over," so that the above rule is not absolute; the degree to which it approaches truth depends on how near the two genes are to one another on the chromosome. Family studies show whether or not two genes are linked, and if so how closely; so that by their aid it should theoretically be possible to build up a chromosome map. Very complete chromosome maps have been drawn up for experimental animals like *Drosophila*, but in man so far a beginning has only been made with the XY-chromosome pair. If it were possible to link rare pathological genes with common normal blood-group genes, a new and powerful technique of genetical analysis of the pathological condition would become available.

Detection of Carriers

Sometimes carriers can be detected more directly by means of family studies (Hsia, 1956; Neel, 1953). Suggestive findings have been made, for example, in diabetes (Pincus, 1934), where relatives are often found to have a low glucose tolerance; these persons may be potential diabetics. In the families of some patients with cystinuria the stone formation can be shown to be due to homozygosity for a gene which can be detected in its heterozygous form. By the technique of paper chromatography the expected proportion of relatives was found by Harris and Warren (1953) to have a raised excretion of cystine. The application of biochemical and other techniques to the relatives of psychiatric patients is perhaps a promising but no doubt complex field for future research and one which might have therapeutic possibilities. Already it has become possible to identify the carriers of phenylketonuria (see page 308). The relatives of epileptics frequently show abnormalities in their electro-encephalogram (Harvald, 1954) which suggest genetical interpretations, though not simple ones. Psychological tests could also be applied to relatives of psychiatric patients with a similar purpose in view.

Assortative Mating

A simplifying assumption which is very frequently made in theoretical genetics is that mating occurs at random. This is far from being even approximately true, and in man is even less true than in other species. In point of fact, the choice of a mate is limited in a great number of ways, so that the population can be, in a rough way, divided into separate inbreeding segments, or "isolates," along a number of dimensions. Thus there are geographical, economic, occupational, religious and many other divisions, within which most matings occur. In general, like tends to mate with like, Briton to marry

Briton, worker to marry worker rather than the Boss's daughter, clerk to marry clerk, Catholic to marry Catholic. This tendency to homogamy is seen also in psychological traits, both normal and pathological. It has already been mentioned that intelligent people tend to marry others of more than mean I.Q., and the stupid to marry those less than average. It is well known that deaf persons often marry one another, as do persons with other disabilities. If a number of genetically influenced conditions occur in one family, the most likely explanation is often neither genetical linkage, nor variability of manifestation, but assortative mating. In Huntington families (Leese *et al.*, 1952) one commonly finds other defects, such as eye conditions, tuberculosis, etc., which have probably entered the one family by selective mating. A study of assortative mating in respect of temperamental traits has shown the same tendency. Slater and Woodside (1951) investigated controlled series of normal and neurotic soldiers and their wives. The wives of the neurotics were themselves more neurotic and came from more neurotic families than those of the normal soldiers, and the dynamic factors involved could be partially clarified.

Homogamy in respect of genetically-determined traits has interesting consequences in increasing the variance shown by a population and in aiding the appearance of pure lines; homozygotes are favoured at the expense of heterozygotes. In itself homogamy is neither eugenic nor dysgenic, but makes the population more susceptible to change from selective influences of either kind. From the social point of view, it helps in the production of specialists of all kinds; we should probably have far fewer capable musicians if musical people did not tend to marry one another.

Fertility

The study of fertility is obviously another one of considerable genetical importance. It has a bearing on population genetics and is of relevance to the future health of the community. The possible consequences for the future of the negative correlation between intelligence and family size is one which has attracted a good deal of attention. A number of studies have shown that, both in the population as a whole and within single occupational groups, the more intelligent have fewer children than the less intelligent. A negative correlation of about 0.2 has been found by most investigators. On the assumption that intelligence is to a considerable extent inherited one would expect a gradual decline in the national intelligence. Summarizing the evidence Burt (1946) calculated that this would amount to 1.5-2 points in I.Q. per generation. If such a trend were to continue to the end of the present century, the proportion of persons with I.Q.s over one hundred and thirty in the population would fall

to less than half the existing figure and that of the feeble-minded would be more than doubled. In 1947 an opportunity occurred to test the prediction that the I.Q. was falling. Fifteen years earlier all the eleven-year-old age group in Scottish schools had been tested with a group intelligence test. When the same age group was tested again with the same test in 1947 by a team of workers under Sir Godfrey Thomson (Scottish Council for Research in Education, 1949), instead of the feared fall in mean score there had been a slight rise. The association between family size and intelligence, however, was as marked as before. There seems to be general agreement that improved environmental conditions and increased test sophistication has contributed to the rise, but it is still an open question whether the improvement due to environment masks a decline in genetical quality. The decline, if real, would stop if the association between higher intelligence and lower fertility ceased to operate. There can be no doubt that the association is susceptible to cultural and psychological influences, and that secular changes occur. In Sweden, family limitation began many years ago in the best educated sections but has now permeated the entire population; the differential fertility, which was once very marked and alarming, is now practically zero. If the well-educated are open to suggestions of the desirability of family limitation, they are also open to the suggestion that the one- or two-child family is disadvantageous, psychologically for the children and perhaps also eugenically for the population. Recent studies of the fertility of university graduates and other favoured classes show a tendency to produce more rather than fewer children (Hubback, 1955; Hutton, 1953; Moberg, 1950; Nesbit, 1955).

In the field of psychological abnormalities, the usual finding is one of lessened fertility (Essen-Möller, 1935; Lewis, 1958). Thus many studies of schizophrenic families consistently show reduced fertility, and the work of Slater and Woodside already mentioned showed reduced rather than increased fertility among neurotics and psychopaths.

POPULATION STUDIES

The discussion of fertility has already led us from family studies to population investigations. It is obviously important from the medical and social points of view to assess the frequency with which different mental illnesses occur in the population as a whole, in different regions or social groups, and in the same region at different times. From the genetical point of view this information is important too. Without knowing the incidence of schizophrenia in the general population it is difficult to assess the significance of morbidity figures obtained for the relatives of schizophrenics. What is required here is

not the crude incidence at a given time, but the number of persons born who might be expected to have had the condition after having lived long enough for it to manifest itself.

Hospital admission statistics are not entirely suitable for calculating the general risk—only a proportion of psychotics and defectives reach hospital. However, Norris (1959) has been able to extract from hospital data a good deal of useful information regarding the incidence of mental disorders in London. By going further afield, estimates can be obtained along three rather different lines. These we may call: (1) the genealogical method, (2) the census method, and (3) the biographical method.

Genealogical Method

The first of these to be developed was the genealogical method. This is really no more than the family method applied to a selected group of persons who are supposed to be representative of the normal population. Hospital patients and their wives are comparatively accessible and have often been used in this kind of investigation. For example, Luxenburger (1928) studied the wives of patients with general paralysis (G.P.I.) in Munich and their families. As the disease is not genetical but due to syphilis, he assumed that these women were no more likely to be psychiatrically abnormal than others of the general population; in fact their families had rather more than their share of G.P.I. On the Danish island of Bornholm, Strömberg (1938) studied the sibs of general hospital patients and persons referred to a T.B. clinic.

Census Method

The samples chosen in the genealogical studies have in some ways not been very widely representative; and this method has been partly superseded by the cross-sectional census survey. The aim of this second method of population study is to ascertain all cases of psychiatric abnormality in a defined area at a given time. The families of the cases notified by official and unofficial sources can then be investigated too. This will bring to light further secondary cases and give information of genetical value. Thus Sjögren (1948) made an intensive cross-sectional study of a typical Swedish peasant population and supplemented it by genealogical research. He utilized for this purpose the very full information that can be obtained from old Swedish parish registers which go back to the seventeenth century.

Among other census-type investigations, we may mention that of Roth and Luton (1943) in Williamson County, Tennessee, and E. O. Lewis's (1929) well-known study of mental deficiency in two urban, two

rural and two mixed areas in England. A more recent British example is Mayer-Gross's (1948) investigation of the incidence of mental disorders in Dumfriesshire. In this work a psychiatric Social Worker, Marjorie Brown, inquired about all patients discharged from the Crichton Royal Hospital during the previous ten years and about their families, and those of present patients. The co-operation of Public Assistance officers, teachers and social workers and ministers of the Kirk was then sought in an effort to ascertain other cases of mental abnormality; and children who had obtained an I.Q. of less than eighty in the eleven-plus examinations were investigated. It is perhaps the use of this last group that is the most distinctive feature of Mayer-Gross's study. It was interesting that the proportion of dullards and defectives among the schoolchildren was twice that found in the total material. The main explanation given for this was that subnormals can easily lead a useful life in that particular community, so that their handicap is hardly noticed after leaving school. In the whole population of 56,000 some 9 per cent were reckoned to be psychiatrically abnormal.

Mental health surveys are most frequently made in rural areas. Here populations are more static than in large towns; people are better known to one another and to those in authority; economic conditions are relatively more uniform. This is all to the good so far as genetic investigations are concerned. But it may be that results obtained in rural areas do not hold good for large towns. A town may perhaps contain less mental defect but more cases of neurosis.

One theoretical difficulty with the census method is that of calculating expectancy rates from the crude figures. Most persons in the population have not reached an age when one can say they will not develop a manic-depressive psychosis—let alone a senile one. Further, psychotics, and especially schizophrenics, have an excessive mortality rate and so will be under-represented in a living sample.

Biographical Method

These difficulties can be met by the third method of population survey—the longitudinal biographical method. Here all persons born in a given year are taken as the starting point of the investigation and then followed up. With this there are even greater practical difficulties than in the census method. Klemperer (1933) was the first to try it out on persons born in Munich between 1880 and 1890, but he could trace only 70 per cent of them.

However, Fremming (1951) applied the biographical method to the Island of Bornholm. He succeeded in tracing 92 per cent of all those born there fifty-five or fifty-six years earlier, including most of those who had emigrated to the mainland. He paid some 2,000

visits to obtain information about over 4,000 persons. Fremming discovered some 12 per cent of them to have suffered from one or more kinds of mental abnormality, a rate strikingly similar to that calculated earlier for the same area by Strömberg using genealogical and census methods. The main difference in the two investigations was that Fremming's method brought to light a considerably higher proportion of manic-depressives, many of whom had never been in hospital and were quite well when seen. Slight drawbacks in the biographical method, apart from its practical difficulties, are: first, the fact that it will not represent present trends but those of a generation or two ago; and secondly no estimate can be given for involutional or senile psychoses unless an investigation group born some eighty years ago is taken.

Incidence of Psychosis and Neurosis

These three methods give estimates for the incidence of the psychoses and mental defect which are very close, considering the many differences between the different countries in which they have been tried out, the various standards of diagnosis and statistical methods used for calculating empirical risk figures. Thus schizophrenia is usually found to have a frequency of between 0.5 per cent and 1.0 per cent; epilepsy one of 0.3 per cent to 0.5 per cent. The rate for manic-depressive psychosis varies more considerably—between 0.2 per cent and 1.6 per cent—largely for methodological reasons. Mental defectives are generally thought to account for about 1 per cent of the population.

So far as neurosis and psychopathy are concerned, agreement is not so consistent, and most figures quoted are probably underestimates. Census studies give rates of about 2 per cent. Fremming gives 5 per cent, Ekblad (1948) who interviewed a large series of Swedish naval conscripts, claimed that 15 per cent of them were psychopathic; he uses the term to cover what in this country we would mostly call chronic neurosis or personality maladjustment. In spite of different methods of approach, high rates are found when the matter is gone into carefully. Russell Fraser (1947) examined a large sample of war-time workers in light engineering factories in the Midlands. He and his co-workers found that 10 per cent of them had lost work during the past six months on account of a temporarily disabling neurotic illness, and that a further 20 per cent had suffered from minor forms of neurosis during that period. Logan and Goldberg (1953) of the Medical Research Council Social Medicine Unit investigated seventy-four lads called up for National Service in a London suburb. Twelve were clearly disturbed with psychiatric treatment considered advisable, and a further nineteen, making 42 per cent in all, were also maladjusted at the time of

the interview. One of the present writers (Shields, 1954), studied a sample of sixty-two pairs of ordinary twins from the L.C.C. Secondary Schools in which it was found that about the same proportion, or nearly half, had at some time or other been neurotic in a broad sense or had presented troublesome behaviour disorders.

While some recent trends in the assessment of mental health involve the intensive investigation of a few cases, Essen-Möller (1956) and three Swedish colleagues have recently shown what can be achieved in the assessment of health and personality traits by short single interviews supplemented by official records. Each psychiatrist averaged eleven to fourteen interviews a day over a period of two months, and together they succeeded in investigating personally 2,500 persons out of a total population of 2,550. The interview took the form of a conversation on the individual's medical and personal history. The area studied was a rural one which included a small municipality and the four investigators divided it equally between them. They assessed personality according to the concepts of Sjöbring. Each individual

was rated on a nine-point scale on each of the three constitutional variants of personality in the Sjöbring system—solidity, stability and validity—and also on capacity (intelligence). Each variant was found to be distributed not quite normally but roughly so. Part at least of the deviations from normality could be accounted for by differences between sexes, age groups and investigators. Some small correlations between the three variants and between these and intelligence were found. No correlation was larger than could reasonably be attributed to systematic diagnostic errors. The consistency between the findings of the four different investigators suggests a fair degree of reliability, especially when the method of investigation is considered. The results are in reasonable accordance with the concept of three mutually independent lines of variation in personality and a fourth, intelligence, each with a normal distribution. Essen-Möller and his colleagues also assessed the presence or absence of personality traits of a more pathological kind, asthenic states and various mental illnesses, past and present, and their inter-relations. We reproduce their cumulative table (Fig. 8.11) showing by sex

FIG. 8.11. CUMULATED PSYCHIATRIC DIAGNOSES, BY AGE AND SEX, IN A SWEDISH RURAL POPULATION

Note. W = women M = men. Among "major personality deviants" are included those who are markedly aggressive, restless, indolent or eccentric. "Asthenic" states are largely characterized by fatigue and nervousness. "Chalaphrenics," in Essen-Möller's terminology, are characterized by a persisting, objective mental and motor slackness or lack of energy. In the diagram "psychosomatic" complaints are grouped with neuroses. Alcoholism is included under asocial behaviour.

(From Essen-Möller, 1956; by courtesy of Prof. E. Essen-Möller and Messrs. Munksgaard)

and age groups the frequency with which the different major psychiatric groupings occurred, proceeding from the most severe to the more trivial. Each individual is counted once only, according to his most severe diagnosis if he had more than one. The reader is left to decide for himself where to draw the line between the normal and the abnormal part of the population. 67·2 per cent of the female and 60·4 per cent of the male living population had collected some psychiatric diagnosis. If we count as abnormal only oligophrenia (i.e. low grade mental defect), severe intellectual deterioration, present psychosis, major personality deviation (more frequent in males) and severe early asthenia (more frequent in females), then 14·9 per cent of the women and 12·3 per cent of the men would be regarded as showing psychological abnormalities. If a further group of persons, including those with severe late asthenia and present neurosis or alcoholism, is included as abnormal, the respective frequencies rise to 47·1 per cent and 34·5 per cent. The authors also make an attempt to estimate how much abnormality has a distinct pathology (including single genes) and how much is due to natural variation. Their analysis of resemblance within families is yet to be published.

Further work is needed to put population studies of personality and neurosis on a firm basis, and to allow the results of one study to be compared with those of another. Easily administered standardized personality tests, to supplement the history and personal observation and to introduce some quantitative measurement, would of course be very helpful, if they could be made reliable. Most tests, at present available, vary too much with the way the subject is feeling at the moment. It is important, also, that we should get to know the frequency, not only of neurosis, but also of those environmental factors, such as a "broken home," which are under suspicion. In researches of this kind there are good reasons for approaching the problem simultaneously from more than one point of view, genetical, social, psychiatric and psychometric.

Study of Isolates: Consanguinity Rate

Apart from surveys of the general urban or rural population, attention has also been given to isolates, or groups characterized by a high degree of in-breeding. One of the advantages of this work is that any genetically determined anomalies are likely to be homogeneous. Böök (1953) recently undertook the arduous task of studying three parishes in an isolated area in the north of Sweden, some thirty miles beyond the Arctic Circle. With the help of his wife, who had been born in the region, he gained the confidence of the population and was able to estimate the frequency and the genetics of the forms of mental disorder and

mental defect found there. Many of the cases of mental abnormality could be consolidated into one pedigree, traceable to thirty-one ancestral pairs. Some of his findings were referred to on pages 309 and 335.

Another investigation, with a primarily cultural orientation, was made by Eaton and Weil (1955) of the Hutterites, a religious sect living in communities of their own in the North of the United States and in Canada. Although these people appeared to be relatively free from neurotic troubles, perhaps because of their simple way of life, there was a high incidence of manic-depressive psychosis, for which the only simple explanation seems to be the genetical one.

In isolates there tends to be a high consanguinity rate in marriage, and this tends to favour the appearance of homozygotes; the result may be seen in a relative abundance of some rare recessive defect. The frequency of cousin marriage, both in the parents of trait-bearers and in the general population, is important to theoretical genetics in several ways. In the general population there are large differences between town and country. In Stockholm only about 0·4 per cent of marriages are between cousins, while in some isolated Swedish parishes the rate may be as high as 6 per cent. It is also likely to be high in minority religious groups. With the breakdown of isolates by the modern growth of communication cousin marriage is becoming less frequent.

HEREDITY AND ENVIRONMENT

The extent to which a given condition tends to run in families is no measure of the degree to which genetical factors are involved. On the one hand conditions with a genetic basis which are lethal at an early age, or are commonly caused by fresh mutation, or are so common as to be nearly universal (such as senile dementia), frequently show no conspicuous familial loading. On the other hand conditions which are independent of gene differences, such as for instance the presence of nits in the hair, may show a marked tendency to a familial distribution. The plausibility of a genetical or an environmental explanation will depend on one's existing knowledge and understanding; and the appearance in siblings of, say, an inborn error of metabolism or juvenile delinquency will be judged accordingly.

The genetical hypothesis can be rejected, if it can be shown that unrelated persons, subjected to similar environments, resemble one another as much as blood relatives. Environmental factors may also be brought out in individual case studies, and by giving special attention to social environment. Were the affected members of a given family subjected to a specific stress (such as separation from their mother at an early age) while the unaffected members were

not? Spouses share a family environment, but differ genetically, and resemblances between them are likely to be environmentally caused, especially where the possibility of contagion, physical or psychological, arises. On this basis, Kallmann and Reisner (1943) included the examination of spouses in their family studies of tuberculosis. However, there are two kinds of material, foster-children and twins, which are particularly suited to the investigation of environmental causes of variation.

Foster-children

The study of fostered, adopted and orphanage children, who unlike other children are not brought up with their own biological parents, enables us, in theory at least, to disentangle the effects of heredity and environment in two complementary ways. On the one hand we can observe the effect of different environments on persons (or groups of persons) who are similar in heredity, as for instance when pairs of siblings are brought up in different homes. Alternatively we can observe the effects of similar environments on persons who are genetically unlike, for example, by comparing "own" and foster-children, or by observing the range of differences among children brought up in the relatively uniform atmosphere of an orphanage.

So far research on these lines has been done mostly in the United States and in the field of intelligence. Woodworth in his monograph entitled *Heredity and Environment* (1941) has summarized and discussed in a clear and fair-minded way the findings of research on foster-children carried out by Freeman and others (1928) in Chicago, Burks (1928) in California, Leahy (1935) in Minnesota, Skodak and Skeels in Iowa (1938, 1939, 1940, 1942) and others.

Attempts have also been made, in particular by the Iowa school to measure the improvement in I.Q. following adoption from an inferior into a superior home. However, the reliability of I.Q.s tested in the early years of life is notoriously low and an improvement in test score after some years might in part be due to the greater security of the child in its new home. Even if it is reliably estimated that adopted children have a higher I.Q. than their (often below-average) mothers, this might well be an instance of the expected "regression to the mean."

Other difficulties in planning and carrying out investigations into foster-children include the practical ones of following up an adequate sample of children placed away from home early in life; moreover, information about their own families is liable to be inadequate, especially in the case of the fathers of illegitimate children. The usefulness of this kind of research is limited too, because the range of foster-home environments tends to be limited. Among

theoretical snags is selective elimination: when one investigates the adopted children of defectives, for example, one finds that their less promising children have not been adopted but retained in institutions, so that the adopted ones are not a fair sample. Selective placement is equally important: if the best children go to the best foster-homes, as is indeed intended when an attempt is made to match the child to the home, this would invalidate the findings. One investigator reports a correlation of 0.3 between "own" parent education and adoptive parent education.

Some investigators emphasize the fact that a good environment can raise by a few very worth-while points the I.Q. of children who come from an unfavourable background. The effect of different kinds of environment on the mean I.Q. of children, believed to be free from the effect of selective placement, is shown in the following findings of Freeman—

45 foster-children in *good* foster-homes scored an average of 112 points.

39 foster-children in *average* foster-homes scored an average of 105 points.

27 foster-children in relatively *poor* foster-homes scored an average of 96 points.

The following table from Leahy shows an apparent influence of the occupational level of the adoptive father on the intelligence scores of adopted children; but it will be seen that there was much less variation between the five adopted groups than between the five groups of "own" children, and that the children adopted into semi-skilled and relatively unskilled families actually did a good deal better on intelligence tests than children born into such families.

TABLE VIII.5
MEAN I.Q. OF FOSTER-CHILDREN AND OF
"OWN" CHILDREN IN HOMES OF DIFFERENT
OCCUPATIONAL CATEGORIES

(After Leahy, 1935)

Occupation of Father	Adopted children		Control ("own") children	
	Number	Mean	Number	Mean
Professional . . .	43	113	40	119
Business manage- ment . . .	38	112	42	118
Skilled trades and clerical . . .	44	111	43	107
Semi-skilled . . .	45	109	46	101
Relatively unskilled	24	108	23	102

The greater resemblance between parents and their own children than between parents and children adopted even early, is also borne out by the work of Burks, who gives her findings in the form of correlation coefficients—

	Foster group		Control group	
	Parents and adopted children		Parents and own children	
	<i>r</i>	N	<i>r</i>	N
Father's mental age	0.07	178	0.45	100
Mother's mental age.	0.19	204	0.46	105

Burks concluded that heredity accounted for about 75 to 80 per cent of the variance in intelligence, under the environmental range from which her sample was taken. Woodworth is of the opinion that, despite their apparent differences, the various studies of the intelligence of adopted children have yielded comparable results; that the method is adequate to bring out any large differences due to the environment; but that scientific precision is not to be obtained.

We may end this section by referring to one of the rare studies of traits other than intelligence which have been studied by this method. It bears out the remarks of Woodworth. In 1945 Roe, Burks and Mittelman reported on the emotional and social adjustment as adults of persons placed for adoption when under ten years of age by a large New York adoption society on account of their parents being alcoholic or psychotic. However, the majority of them either could not be traced or did not co-operate in the study. Over one-third of those seen showed evidence of various sorts of maladjustment, but with few exceptions they were living useful lives. Only very few were professional workers, though many of the foster-homes were of professional standing. This is probably not a bad result, all considered, and it is perhaps better than would have been expected if the children had remained in their unstable home environments. But as the persons with whom no contact was made may well have included an undue proportion of social failures, even so tentative a conclusion as that is hardly justified.

Twins, the Two Kinds

Twins can give us information both about specific environmental factors and about the relative importance of heredity. This is because there are two kinds of twins. There are the uniovular or monozygotic (MZ) pairs, which are derived from a single fertilized ovum, which has split into two (or sometimes more) individuals at a very early stage; and there are the

binovular or dizygotic (DZ) pairs, formed by the fertilization of two different ova by two sperms. The latter are no more alike genetically than an ordinary pair of brothers or sisters, and are often known as fraternal twins; they can expect to have no more than half their genes in common. Monozygotic twins, however, should be duplicates of one another in respect of each and all of their genes, and can be regarded as genetically "identical." MZ twins are sometimes rather different in appearance, and DZ twins can be extremely alike, so that it is occasionally difficult to allot a pair of twins to their correct biological class. The usual and best method of determining ovularity is to test the pair for similarities in respect of a number of traits, of a kind in which genetical causation predominates, such as eye colour, blood groups (Smith and Penrose, 1955) and fingerprints (Nixon, 1956). By such means the probability of an error in classification can be reduced to a level at which it can have no material effect in the comparison of two series.

Differences between Monozygotic Twins

When we compare MZ twins, we know that differences between them must be due to non-genetical causes. Some differences might be due to factors operating before birth, rather than to the post-natal environment. Influences of this kind are perhaps rather liable to occur in twins. Asymmetrical features, for example, such as the hair whorl going in opposite directions or one twin being left-handed and the other right-handed occur more frequently in twins than in the singly born (Newman, Freeman and Holzinger, 1937). With monochorionic pairs one twin may secure for himself more than an equal share of the placental circulation (Price, 1950) and this can lead to a significant difference between identical twins in birth weight. Both these factors should be borne in mind in interpreting the findings of twin studies. However, their influence in psychiatry is probably not very great; they might be more important in connexion with congenital abnormalities. Twins of both kinds, particularly MZ twins, have a lower birth weight and are less viable (Allen, 1955) than non-twins; the mean I.Q. of twin children is 5 points below the average for all sizes of family (Barclay and Maxwell, 1951). But if they survive the initial risks they probably grow up to form a fairly representative cross-section of the population; except possibly for certain forms of mental defect and epilepsy, the incidence of mental illness is not raised in twins. For instance, twins are no more often referred to the Maudsley Hospital than are singly-born persons (Shields, 1954). When we investigate a complete series of twins with a single condition we are probably making a fair sample of that condition.

Information about the post-natal environment can be obtained from identical twins in a number of ways.

Co-twin Control

According to Gesell's (Gesell, 1941) "co-twin control" method, one infant twin is trained in an activity such as stair-climbing, while the other twin is not given the training, and the effect of this is observed. The possibility of much direct experimentation in this way is of course limited, but the method could perhaps on occasions be applied, and not only to children (Glass, 1954). In cases where a pair of adult MZ twins have the same illness equally severely at the same time the effect of different treatments can be studied.

A less experimental application of the co-twin control method consists in making careful observations of twins in infancy and predicting the possible consequences of the similarities and differences and personal relationships noted at the time. In follow-up studies these predictions can then be tested.

Case Study

However, in psychiatric twin studies, as in ordinary clinical work, the retrospective case history method generally has to be used. Here the life histories of a pair of twins are compared and any differences between them in psychiatric status are related to their past experience or way of life (Slater, 1953). From the study of many pairs on these lines one can perhaps reach conclusions of general relevance to the causes and prevention of mental ill-health.

Twins Brought up Apart

One limitation of twin research as a means of assessing the influence of the environment is that we are normally confined to pairs who have been brought up in the same home and so have had similar experiences; and differences between MZ twins brought up together must often be attributed to the relations between them rather than to wholly external factors. However, twins brought up apart are very hard to come by. Over a period of years Newman, Freeman and Holzinger (1937) in America succeeded in investigating only nineteen such pairs of MZ twins, and to obtain this number many had to be bribed by a free visit to the World Fair in Chicago. Newman and his colleagues found that these twins, who were mostly adult, resembled one another in intelligence less closely than MZ twin schoolchildren who had been brought up together in Chicago, but they resembled one another more closely than DZ twin schoolchildren. There was a high correlation between the amount of formal education received and Binet I.Q. The difference between the MZ pairs brought up apart and those brought up together can be accounted

for very largely by a few pairs where there was a rather extreme difference in their backgrounds. Thus in one of these pairs, one twin had only two years' schooling while her partner had a college education and was herself a schoolteacher. They differed by 24 points in I.Q. Small inter-family differences had little effect on intelligence. In personality, correlations between twins were lower than in intelligence; this may have been largely because of the tests used, but here again the separated identical twins were on the whole no less alike than those brought up in the same home, and a number of clinical similarities were noted.

Craike and Slater (1945) have described a pair of MZ twins who were separated at nine months and who both developed paranoid schizophrenic illnesses later on. Kallmann (1938) has also described a pair of this kind, and yet another case has recently come to the notice of our Unit.

Through a television programme the B.B.C. recently brought to light a considerable number of normal MZ twins brought up apart, and some forty of these have so far been investigated at the Maudsley Hospital. They include all degrees of separation during childhood. Thus, there is a pair in which one twin was adopted by a well-to-do family in Chile and married a Frenchman. The other was brought up mostly in Denmark in poor circumstances with a psychopathic father, and she married an Englishman. In another pair, twin boys were brought up in separate homes from birth, but by different aunts living only next door to one another. It is interesting to compare the effects of different degrees of separation. The cases where the separations were not very extreme, such as those where one twin was brought up by mother the other by grandmother, are important for the opportunity which they give for assessing the significance of such factors as the age and personality of the mother, the presence of other children in the family, a town or country environment and the mutual influence of the twins.

From the results so far, age at separation does not appear to be of very great importance—the few pairs separated after the age of four differed as much in personality as the majority who were separated soon after birth. Nor does childhood contact with the twin appear to have made for greater similarity. One of the most strikingly similar pairs had no knowledge of one another until they were reunited by the research at the age of 36. On the whole the kind of home made a bigger difference than the degree of separation. In the pairs that differed most psychiatrically there was generally some definitely unsatisfactory feature in the early environment of the twin who had the poorer mental health. Differences in social class, though not marked in the series, could be seen to

have an effect in causing differences of behaviour. However, the respective foster-parents of the two twins could differ quite a lot in age, personality and ideas of bringing up children, without this necessarily resulting in any obvious differences between the twins. Many striking similarities in speech, gesture, interests and temperament were noted. The results of a simple personality questionnaire, devised for us by Professor Eysenck, lend support to the observation that twins brought up in different homes can resemble one another closely in personality. For extraversion there was a positive correlation between twins of 0.60, for neuroticism one of 0.52. For intelligence the correlation was 0.77 on a non-verbal test. (Newman reported a correlation of 0.67 for Binet I.Q. between his separated MZ twins.) A preliminary account is given by Shields (1958).

Comparison of Resemblances within MZ and DZ Pairs

If MZ twins are alike in a particular respect, one cannot conclude that this is because of their possessing the same genes; it might be due to their similar environment. To help us decide this point we have the DZ—or hereditarily non-identical—pairs. If sex is a significant factor then the DZ pairs of the same sex can be compared with the MZ. One could hardly find individuals brought up in more similar environments than twins. Both kinds are born into the same home at the same time with all that this implies; they are more alike in this respect than ordinary siblings. If, in a representative series of pairs, the average resemblance between the MZ twins is markedly greater than that between the fraternal twins, then there is a strong case for the view that the genetical constitution has an important bearing on the condition in question, at least under present circumstances.

Psychological factors. An objection sometimes raised against a comparison of MZ with DZ twins is the fact that the former tend to go about together in childhood and are sometimes unusually closely attached to one another, while fraternal twins often develop more independently and so do not have quite so similar psychological environments. The influence of this might be quite important in some conditions, particularly in childhood; but in others it would be negligible. However, any difference of this sort between the two kinds of twins is largely a reflection of the innate needs of the twins themselves. Everyone tends to make his environment for himself, as well as to be influenced by it. One can, of course, test by observation whether those MZ twins who are most closely attached to one another are in fact more similar psychologically than the others. From our own (Shields, 1954) experience with normal London schoolchildren this did not seem generally to be the case. There is, however, another psychological factor

—one making for difference between MZ twins; this is the tendency with many of them for one to be the dominant partner, the other to be more submissive. Certainly it would be most implausible to explain any differences in resemblance between MZ and DZ twins entirely by external environmental factors, such as the ways mothers treat their twins. For this to be the true explanation, nearly all mothers would have to treat their MZ twins in exactly the same way, but handle DZ twins of the same sex very differently indeed. This does not appear to be the case at all. Some tendency of this kind may be forced on the parents by the twins themselves, but it is probably to a considerable extent offset by a reaction in the opposite direction. Mothers of MZ twins often like to think of their twins as different so that they may regard them as separate individuals. The mothers of DZ twins generally make the most conscientious efforts to give their twins the same of everything. Points such as these can often be clarified by actual case studies of twins. Further, as we have seen, the findings on twins brought up apart vindicate some of the presuppositions of the traditional twin method.

Unselected series. It is just as important in collecting a twin series as in other types of family investigation to guard against bias in selection. The field from which the collection is made must be defined, and within it the collection should be unselective and as comprehensive as possible. It has been shown (Luxemburger, 1930) that reliance on published case reports leads to a gross bias, as pairs of twins in which both members show the trait greatly preponderate. In any investigation in which there is any casualness or informality in ascertainment the same sort of bias is likely to arise; for some reason nearly everybody, including doctors, find twins who resemble one another much more interesting than twins who differ.

If an unselected series can be obtained, then estimates of *concordance rates* become interesting. A pair of twins is said to be concordant in respect of some trait if both members are alike in showing or not showing it, discordant if one shows it while the other does not. If the trait in question is wholly genetically determined, we shall expect all MZ twins to be concordant, but the concordance rate in DZ twins will depend on the mode of inheritance and frequency of the gene in the population. Thus, if we collect twins who (1) belong to blood group O, (2) have Huntington's chorea, (3) have phenylketonuria, the concordance rates which we shall expect to find in their DZ partners will be respectively (1) 70 per cent, (2) 50 per cent, (3) 25 per cent. From this it follows that no sound measure of degree of genetical determination can be obtained by simply setting the concordance rates in MZ and in DZ pairs in relation to one another. In the case of continuously distributed

variables, the correlation coefficients within MZ and DZ pairs may be contrasted; and Holzinger has suggested his h^2 formula (see page 331) to combine both in an estimate of degree of genetical determination. This too cannot be regarded as fully reliable; and the best plan is to consider the meaning of the concordance rates found, in the total setting of the experiment.

From studies of twins alone one can obtain no information about the mode of inheritance. For this the twin and family methods can usefully be combined; a series of twins is obtained, and then not only their twin partners but other members of their families are investigated. Such a study will also provide information, through a comparison of probands with their singly born sibs as well as with their DZ partners, about early environmental influences; if these are important, DZ partners should be more alike than proband and sib.

Twin series of any useful size can only be obtained if the trait investigated is a common one; but within this field the method is a most useful one, particularly if the aetiology is obscure. A comparison of concordance rates in MZ and DZ twins provides a sensitive test of significant genetical causation. For

this reason, such studies have proved particularly valuable in psychiatry, for psychiatric abnormalities tend to be very common, and also to be obscure. The table above shows some of the concordance rates which have been found in a great variety of conditions, from which a lesson may also be learned on how to interpret these figures (Table VIII.6). If, for instance, we contrast the rates in measles with those in mumps and in polio, a shift in the degree of genetical participation will be seen, even though in all three the specific cause of illness is a foreign agent. In the case of measles, it would seem that nearly everyone who meets the germ gets the illness, and that there is very little variation in individual susceptibility. In the case of mumps, there is much more variation in susceptibility, but, since there is little difference between MZ and DZ concordances, this variation must be largely non-genetical. Only in the case of polio, of these three, is there a strong suggestion that hereditary constitution may be a matter of moment.

Psychiatric Abnormality in Twins

Mental deficiency. The best investigation in the field of mental deficiency is that of Juda (for references see Table VIII.6). She studied the children attending

Special Schools in Munich, and made a complete ascertainment of the twins among them. Excluding cases where the defect was caused by birth injury or other possible exogenous causes, the MZ pairs showed 100 per cent concordance; that is to say, in every case the twin partner of the *propositus* or index case was also mentally defective to some extent. In fact, in fifty-five out of sixty twin pairs both had the same grade of deficiency. In the DZ pairs 58 per cent of the partners were concordant, but in only half of them were both twins affected to the same degree. The findings are consistent with the view that most cases of undifferentiated mental defect are of primarily genetical origin, and that environmental factors, at least those that can vary within the family, are of little significance. Juda's findings are in good agreement with those of Rosanoff in the U.S.A., who, without distinguishing cases of defect of known aetiology, found concordance rates of 91 per cent for MZ pairs, 53 per cent for DZ pairs, in a series of three hundred and sixty-six twin pairs.

Schizophrenia. The work of Luxenburger in this field is the pioneer work on psychosis in twins. In 1928 he drew attention to the necessity of working systematically, and recommended the ascertainment of the twins in a mental hospital population by checking in the birth registers. Doing this in a defined population of 16,000 schizophrenics, he discovered twenty-one who had MZ twin partners who had survived into an age of risk; in fourteen of these pairs both members were schizophrenic or probably so, in the other seven only one member was affected. Very similar figures have subsequently been found by Rosanoff, Kallmann and Slater; but in cases where a twin partner has not yet fallen ill allowance should be made for age at observation, and where this has been done age-corrected figures are given in the table.

A very large initial clinical material must be investigated before a large enough number of MZ twins with a given diagnosis and with a surviving partner can be assembled. Fraternal twins are of more frequent occurrence, but if the condition is one in which they are not often concordant, the sampling error of the concordance rate may be high. Thus in Luxenburger's series there were forty-eight DZ pairs, and in not one was the partner certainly schizophrenic. Kallmann and Slater, on larger material, have each found a concordance rate of 14 per cent, which is also given by Kallmann for the incidence in the sibs of schizophrenics. Kallmann's latest report is based on no fewer than nine hundred and fifty-three schizophrenic twins and their families. In accounting for the discordant MZ twins—only about 14 per cent—Kallmann lays great stress on body build and weight. He found that when one twin fell ill and the other did not, or when one twin was much more severely

ill than the other, it was the more asthenic twin who fared worse.

In the mental hospital material we have investigated from the Maudsley Hospital, we found a somewhat lower MZ concordance rate than Kallmann, one of 76 per cent; twenty-eight of the MZ partners of forty-one schizophrenics were also affected. Besides many close clinical similarities there were also some striking differences. For example, in one case one twin spent eighteen years in hospital, the other four months only. In about half the pairs the twins fell ill within two years of one another; but in one case one girl became schizophrenic at 16, her twin not until 47. This material was given a detailed analysis and description, so that some conclusions could be drawn about the features of the environment and of the personality associated with differences in mental health, and about the features of the illness which showed or did not show indications of genetical determination. The modern trend in twin research recognizes the value of detailed individual analysis, in addition to mass statistics.

Another detailed study is by Essen-Möller. He investigated a small but representative series of twins from a psychiatric clinic in Sweden, and brought to light many differences in severity. However, when both twins had some psychiatric disorder in which there were schizophrenic features in one, these tended to be present in the other too. He found it necessary to formulate the diagnosis in a more fluid way than the other workers mentioned, as many of the psychotic states were atypical. It is not easy to say just what the concordance rates were.

Affective psychoses. Studies on manic-depressive twins have not been carried out on such a large scale, but those that have been made give similar results. Kallmann found in twenty-three MZ pairs that twenty-two of the partners were similarly affected, against figures of 26 per cent for DZ twin partners and 23 per cent for sibs. Once again he found that the physical constitution was important, the less severely affected individuals being less obese. His work on involutional psychoses indicates that they should be distinguished from manic-depressive syndromes. MZ twin partners of involutional depressives were similarly affected in 61 per cent of cases; but he found also a raised incidence of schizophrenia among their relatives. In previously reported work from our Unit, we have had too small a number of manic-depressives to draw any conclusions. But in a recent series of sixty pairs, investigated here by da Fonseca and recently published in Portugal, results on the whole are in conformity with those of other studies. Da Fonseca's concordance rates as given in the table include partially concordant cases, i.e. those where the co-twin had an abnormal personality of a depressive

or hypomanic kind. If overt illness is taken as the criterion the percentages concordant are reduced to 60 per cent and 31 per cent for MZ and DZ pairs respectively. Concordance for cyclothymic personality was higher than that for affective illness.

Senile psychoses and senility. It is once again to Kallmann that we are indebted for twin work in this field. He found a concordance rate in MZ twins of 43 per cent as against 6.5 per cent for DZ twins; and the incidence of such conditions in their other relatives was higher than in the general population. Studying a series of twins, selected only for having outlived the age of 60, he (1951, 1953) found that MZ pairs, even those who had lived apart for many years, showed a closer resemblance in intelligence, longevity and manner of ageing, than DZ pairs.

Epilepsy. The two principal investigators in this field have been Conrad in Germany and Lennox in the U.S.A. The work of the former is a model of thoroughness, but it is restricted to institutionalized epileptics. Lennox's material includes out-patients. In both studies a remarkably high concordance is reported for MZ twins, 86 and 88 per cent when cases of epilepsy due to acquired brain damage are excluded. Where there was a known or probable cause of local brain damage, the MZ rates were very much lower. This provides an example of the use of twin studies to throw light on the validity of diagnostic classification, and shows that the now somewhat suspect term "idiopathic epilepsy" does have a real meaning. It seems unlikely that, however far our methods of neurological investigation progress, we shall find a specific local cause for every case of epilepsy; in a considerable proportion of cases a constitutional instability must be the main factor.

Male homosexuality. A number of workers have reported single cases, or small series of cases, of homosexuality occurring in twins; however, Kallmann's series is the only thoroughly systematic one. He and his team had great difficulty in carrying it out, as their contacts showed the greatest reluctance to come to the Research Institute, and wished to be interviewed, if at all, in resorts which were familiar to them.

Out of Kallmann's (1953) eventual total of forty-five MZ twin pairs, only one was discordant; and in that case the homosexual twin was also, unlike his brother, schizophrenic. The other *propositi* in this series were confirmed homosexuals with a high rating on the Kinsey scale. A full classification of the DZ twin partners has only been given for the first twenty-six pairs (in 1952); of them one reached a grade of 5 or 6; two a grade of 3 or 4; eight a grade of 1 or 2; and fifteen were in the 0 grade. This is no higher an incidence of homosexual traits than Kinsey found for the white male American population on which he

worked. It is possible that Kallmann's material is influenced by a selection in favour of severity and constitutional predisposition, and that his figures would have been different if he had started with younger homosexuals. Nevertheless, the evidence is, of course, very strongly in favour of a genetical factor in the type of homosexuality which Kallmann studied.

Suicide. As a contrast with the above figures, we may mention Kallmann's (1953) work on suicide. A prolonged search of the literature disclosed no case of both of a pair of twins committing suicide—unless it were together in a suicidal pact; eventually one such case did come to his notice, and another has recently been reported by Dencker (1957). Though heredity may perhaps play some part in causing a melancholy disposition, suicide itself must require precipitation by accidental factors, such as sudden environmental pressures. This illustrates the relationship and the contrast between personality and behaviour, which have been more intensively investigated in the field of crime.

Crime. The first study of significance was carried out by Lange, who was so impressed by his findings that he entitled his report *Crime as Destiny*. Only three out of his thirteen MZ pairs were discordant, and in very few of the DZ pairs were both twins criminal. These results have not been subsequently confirmed, and later workers, such as Kranz and Stumpfl, have found concordance rates of about 60 and 40 per cent in MZ and DZ twins respectively.

The difference is not so great as to make one think that heredity plays any strongly preponderant role. The high concordance in DZ twins underlines the significance of early family background; and the 40 per cent discordance in the MZ twins supports the idea that special opportunities and temptations have to be regarded as important.

However, detailed clinical studies show that accident plays a smaller part, and personality a larger one, in the case of severe and persistent offenders. Some of the subjects were of a kind to drift naturally into a criminal career, and if so, the MZ twins generally resembled each other in this too. Crimes of violence in one twin would be matched by violence in the other; or both of the twins might be confidence tricksters or swindlers of a similar type, or petty larcenists, or sexually deviant. In some cases, behaviour, though similar, fell one side of the line of legality in one twin, on the other side in the other; or one might find the socially acceptable equivalent of what in the other became a transgression. By and large, it could be shown that whereas personalities resembled each other closely, the range of behaviour available to anyone of a given personality was surprisingly wide.

Included in Table VIII.6 are data from the first report of what should be an interesting study by Kaij

of the *drinking habits* of twins. These were considerably more alike at all levels in MZ than in DZ pairs but the figures suggest that it can fairly often happen that one of the MZ twins is merely an above-average consumer, while the other ranks as an addict or chronic alcoholic.

Rosanoff's findings on *juvenile delinquency* show the very high concordance rate of 86 per cent for MZ twins—but an almost equally high one of 75 per cent for the same-sexed DZ twins. These findings resemble those of measles and mumps, rather than schizophrenia and epilepsy. Environmental factors have to be ranked high in importance, and among them, especially in juvenile delinquency, we have to take into account the influence of one twin on the other. On the borderlines of neurosis, we note that *behaviour disorders* in children are not so concordant in DZ pairs as is juvenile delinquency; such phenomena are likely to be a closer reflection of the personality than is delinquent behaviour in the young.

Neurosis. Twin studies in this field have been surprisingly deficient in number and scope. In published material from our Unit, in only two out of eight MZ pairs was the second twin likewise neurotic or psychopathic. In a subsequent study of school-children, it was found that most MZ twins, while far from being replicas of one another psychologically, tended to be similar in temperament, and that when both had neurotic traits these were generally of the same kind. Even more striking were the differences within DZ pairs; if both of such a pair were neurotic, the symptoms were usually different. On the other hand, the appearance of behaviour disorders in a family was related to the poorness of the psychological environment. To over-simplify somewhat: type of reaction seemed to depend a good deal on constitutional factors, whilst severity was more closely related to the environment.

In continued work at our Unit, mainly on post-war Maudsley neurotic twins, we have found concordance rates of about 53 per cent in MZ twins and 25 per cent in DZ twins. This is using the objective but possibly somewhat trivial criterion of having been referred to a psychiatrist or, in the case of children, to a juvenile court. Such an arbitrary definition of "neurosis" does not have much meaning; and the crude concordance rates do not do justice to the personality resemblances.

These figures show that hereditary constitution is a factor of some significance in neurosis; and detailed case study can add information on the variability of expression of some constitutional characteristics. But such material is also interesting in providing the means by which one may analyse the environmental causes of neurosis, by investigating the histories of twins who have differed. Even the concordant pairs

are of use in this connexion, as there are frequently marked differences in the degree of a neurotic reaction. It would seem inapposite to classify all these reactions as pathological, or abnormal in more than a statistical or social sense. They are modes of behaviour which lie within the potentialities of the average normal person; and their causation is invariably multiple and complex. The twin method proves a very useful method of separating out some of the threads which enter into the tangle.

Psychology and Genetics

In the sections illustrating the various modes of inheritance and methods of research, we have made reference to many of the salient investigations in the field of psychiatric genetics. In this final section we propose to cover in a brief and synoptic way the present state of our knowledge of hereditary factors as they enter into particular types of psychological abnormality.

ABNORMALITIES OF PERCEPTION

Defects of *vision* may be caused by abnormalities of any part of the visual apparatus, from the cornea back to the higher association centres in the brain. Errors of refraction, long-sightedness, short-sightedness, astigmatism, are of course common, and frequently involve the participation of genetical factors. A man with a good "eye" may not necessarily be one who can see the moons of Jupiter, but rather one whose speed and accuracy in oculo-motor co-ordination enables him to excel at, say, tennis or cricket. The investigations of Galton (1869) have shown that proficiency in sports of many kinds runs in families, and this cannot be solely through a favouring family tradition. We have discussed colour-blindness under sex-linked inheritance; the defect is probably of a biochemical kind, involving the deficiency of a pigment in the retina. *Retinitis pigmentosa* is a disease affecting the retina, genetically determined, and leading to progressive loss of vision proceeding from night-blindness to total blindness. Alström (1957) found that about 10 per cent of the persons admitted to the Swedish government's school for the blind suffered from some form of blindness due to the same recessive gene. As an example of a defect in the highest nervous centres we have congenital *dyslexia* or word-blindness, which Hallgren (1950) has shown to be almost certainly due to a dominant gene.

Defects of *hearing* (Lindenov, 1953) are most commonly caused by infections of the middle ear, and so are essentially non-genetical. However a chronic disease of the middle ear, otosclerosis, tends to run in families, and is responsible for a large group of persons who become deaf in later life. Hereditary

factors are more extensively involved in diseases of the inner ear and of the auditory nerves and their connexions, but little is known of their genetics. Among higher nervous abnormalities deaf-mutism when genetically caused is generally due to one of a number of different recessive genes (Stevenson and Cheeseman, 1956). Tune deafness (Kalmus, 1949) may be due to a dominant.

Of *other sense deficiencies* still less is known. Taste-blindness to phenylthiocarbamide (Snyder, 1932) is due to a recessive gene, and the inability to smell potassium cyanide is possibly due to a sex-linked recessive gene (Kirk and Stenhouse, 1953). According to Malan (1940), differences in the capacity for spatial orientation are largely inherited.

ABNORMALITIES OF INTELLIGENCE

We have already discussed in some detail the evidence that goes to show that the observed normal variation in intelligence can be satisfactorily accounted for by polygenic inheritance, with environmental factors playing a smaller but still substantial role. Variation of a pathological kind, in the I.Q. range below 50 per cent and including idiots and imbeciles, may also arise from genetical causes as well as from environmental ones such as birth trauma. Genetical factors are likely to be of the single-factor kind, such as the recessive gene of PKU. Twin studies have shown that genetical factors are important in cases of deficiency that find their way into institutions and special schools.

To this evidence we may add the results of twin researches in the physiological range, in which intelligence tests have been used. In the earlier work on these lines ovularity diagnosis was generally inadequate. However several workers (Thorndike, 1905; Merriman, 1924; Wingfield, 1928; Tallman, 1928; Verschuer, 1930; Herrman and Hogben, 1933; Newman, Freeman and Holzinger, 1937; Blewett, 1953, 1954; Strandkov, 1955; Thurstone, 1953; Vandenberg, 1956) have found that MZ twins show a closer resemblance in I.Q. than DZ twins. For instance, Newman *et al.* tested fifty MZ and fifty-two DZ pairs of schoolchildren with the Binet test, and obtained correlation coefficients of 0.88 for MZ and 0.63 for DZ twins.

Holzinger (1929) introduced the statistic h^2 as an index of heritability, the environment being held constant. This is calculated from the formula $(r_{MZ} - r_{DZ}) / (1 - r_{DZ})$, a procedure which is not free from logical objection (May, 1951), although it has been much used. On Newman's material, h^2 was 0.68.

Eysenck has stated that correlations between the factor score derived from a battery of intelligence tests would give a truer picture than a single test.

Blewett (1953, 1954) carried out a study on these lines, using five scores from Thurstone's Primary Mental Abilities test (verbal, space, reasoning, number and fluency) and Furneaux's tests of speed and power. His factor scores gave rather lower correlations than those obtained by Newman, 0.76_{MZ} and 0.44_{DZ}. The hypothesis that the factor score would prove to be more highly determined by heredity than any of the scores from single tests was not borne out. A higher h^2 was obtained for verbal (0.68), fluency (0.64), and reasoning (0.64) than for the factor score itself (0.58). However, Eysenck (1956), analysing the results of tests applied by both Blewett and McLeod to the same twins, found that tests of finger dexterity and rigidity had high loadings on intelligence. Including these tests, the factor score gave higher correlations, 0.82_{MZ} and 0.38_{DZ}; $h^2 = 0.71$.

The use of a test such as Thurstone's P.M.A. should enable one to discover whether one aspect of intelligence is more highly inherited than another. Thurstone and his colleagues (1953) ranked the separate abilities in the order of the significance of the difference between the scores of forty-eight MZ and fifty-five DZ pairs; the order was space, verbal, fluency, number and reasoning. Vandenberg (1956) makes a rough comparison of the within-pair variance of forty-five MZ and thirty-seven DZ twins for a variety of psychological and other traits, diagrammatically and without giving numerical results. Of the traits probably related to intelligence the largest MZ-DZ difference was in P.M.A. sentence completion, followed successively by the Stanford spelling test, the W.I.S.C. vocabulary test, P.M.A. arithmetic, Raven's Progressive Matrices, and finally, with very little difference between the two kinds of twins, mechanical insight. The results of these investigations are not easily compared with one another, owing to the different ways in which the findings are presented. In all of them, however, verbal ability shows up as one of the most highly inheritable aspects of intelligence within the family.

Taking intelligence as a whole, a number of attempts have been made to estimate the proportion of the total observed variance which can be attributed to heredity on the one side and environment on the other. We have already mentioned Burks's (1928) estimate of 75 to 80 per cent attributable to heredity. Burt, in a paper published in 1943, summarizes extensive work done on this subject under his supervision; and more recently (1955) he has given his opinion that very nearly 90 per cent of the variance in intelligence exhibited by a complete age group is attributable to the genetic constitution of the various individuals, while approximately half of this could be predicted from the characteristics of near relatives. Godfrey Thompson, Hogben (1933) and others have estimated

the contribution by heredity as rather lower, nearer to 60 per cent. In connexion with all such estimates, it must be remembered that only that degree of genetical and environmental variance which obtained in the circumstance of the experiment will be measured, and that this will be, on both sides, very much less than what obtains in the population at large. A group of L.C.C. schoolchildren, for instance, must come from a much more homogeneous environment than the population of Great Britain as a whole, not to speak of the population of the world. Generalizations on this subject must, therefore, be made only with great caution. Other authorities consider that the interaction of heredity and environment is so complex that it is probably futile to try to inquire into the extent of hereditary determination (Anastasi, 1954; Carter, 1940; Jones, 1955; Langfeld, 1951; Thompson, 1954). Nevertheless much can be learned from attempts to do so.

ABNORMALITIES OF CHILD DEVELOPMENT

There is a wide range of normal variation in the rate and pattern of maturation. This is to a large extent genetically determined (Tanner, 1953). Twin studies show that MZ twins resemble one another more closely than DZ twins in the age at which they begin to talk (e.g. Bossik, 1934; Verschuer, 1927) and in the tests of development of Hetzer and Bühler (Lehtovaara, 1938). Russian studies on a small number of pairs showed that the height of jump attained by four-year-old twins was much more alike in MZ than DZ pairs (Mirenova, 1934). The Vineland Social Maturity Scale has been administered to twins by von Bracken (1939), Wilson (1941) and by Troup and Lester (1942). All report negligible differences between MZ twins and larger ones between DZ twins. There is probably an important genetical element controlling the rate of sexual maturation as shown for instance by the greater mean difference in age of first menstruation reported by Petri (1934) for DZ twins (12.0 months) than for MZ twins (2.8 months). However, mothers and daughters showed no closer resemblance in this respect than pairs of unrelated women, thus suggesting, as Stern (1950) points out, that differences in family environments and differences between one generation and the next are important too.

It is not suggested that any of the above developmental stages are entirely genetically determined or that they are simple, well-understood processes. But the combined influence of heredity on many aspects of development must be considerable and will play its part in determining many abnormalities of development, for example in psychosexual maturity. Luchsing (1940) reports that speech development, especially retardation in speech, is largely hereditarily

determined. We have already had occasion to refer to Hallgren's (1950) detailed study of backward readers. In her series of twins at Special Schools in Munich, Juda (1939) found three cases of MZ pairs where both were genuine late developers. In Kallmann's (1956) large twin material he discovered fifty-two cases of schizophrenia commencing before the age of 15. Twelve out of seventeen MZ co-twins also developed schizophrenia under the age of 15, and six out of thirty-five DZ co-twins. Pre-adolescent schizophrenia appeared to be a special case of adult schizophrenia, and three MZ and two DZ co-twins became schizophrenic after the age of 15.

Turning to minor disturbances of development, as seen for example in some of the commoner neurotic and behaviour disorders of children, the influence of the genes can perhaps be seen in the observation of Shields (1954) that when a pair of twins both have some trouble of this nature the symptoms are generally of the same kind in MZ twins but different in DZ twins. For instance, he reports six pairs where enuresis occurred in a MZ pair and in four of these both twins were similarly affected. There were ten DZ pairs where this symptom occurred and in none of them were both twins enuretic, though in some cases the twin partner had some other trouble. In a recent monograph Hallgren (1957) has attempted to clarify the part played by the constitution in this disorder, finding quite strong grounds for believing there to be a considerable genetical element in primary enuresis. However, childhood behaviour disorders are very common, often transient and often demonstrably reactive to unsatisfactory external circumstances. Faulty learning habits are also no doubt often to blame. The role of the genes will be relatively indirect.

PSYCHOPHYSIOLOGICAL TRAITS

In 1944 Jost and Sontag showed that similarities in autonomic response increased with the degree of genetic relationship. Earlier work on pulse-rate and blood-pressure in twins received confirmation and elaboration when Eysenck (1956) extracted an "autonomic" factor from the data of Blewett and McLeod. The scores of MZ twins on this factor had a correlation of 0.93, those of DZ twins of like sex one of 0.72; the factor was highly influenced by sex. Carmena (1934) tested the psychogalvanic reflex of thirty-six MZ and twenty-four DZ twins and concluded that nervousness and kindred temperamental traits were the result of hereditary influences. According to Kanaev (1938) MZ twins show striking similarities in the ease with which they can be conditioned. Similar abnormal electro-encephalographic records in relatives have been reported, though the work of

Harvald (1954) shows the mode of inheritance of EEG pattern to be a complex matter. Nevertheless, Lennox (1945) considers that in certain circumstances EEG patterns can be used as a criterion to distinguish MZ from DZ twins.

PERSONALITY

The relationship between autonomic factors, P.G.R., conditionability and EEG on the one hand, and personality characteristics, such as nervousness, extraversion and aggressiveness on the other, have been mentioned in the main body of the book. Body-build too, possibly through its relation with autonomic functioning, has well-known associations with personality and is genetically determined to a substantial degree. But the connexion between physiological make-up and personality is one of some fluidity. Thus Whelan (1951) reports a pair of MZ twins, both of whom had similarly abnormal EEGs of an epileptic kind; yet one behaved in an extremely psychopathic way, aggressive, antisocial and subject to fugues, while the other was psychologically and socially within normal limits.

When attempts are made, generally by means of the twin method, to investigate personality characteristics at the level of motor activity, positive findings as regards heredity are usually found. Thus Luchsinger (1940) found heredity to be an important determinant of posture, throwing movements and mimicry. Lehtovaara (1938) made cinematographic records of twins watching a film. The course, character and intensity of the mimical process was much more alike in the MZ pairs. Also using film studies of twins, Spindler (1955) found an important hereditary basis for emotional and expressive mobility in adults, but not for voluntary movements. MZ twins are frequently reported as having indistinguishable voices. Gedda and his colleagues (1955) have found that when recordings of their own voices and those of their twins were played back to a group of uniovular twins, they were as a rule unable to tell one from the other. Family resemblance in physique predisposes towards similar interests and abilities in sport and athletics such as are often found in father and son, in siblings, and particularly in MZ twins. Galton's observations on the subject have already been noted and Grebe (1955, 1956) has made some interesting observations on sporting abilities in twins and other relatives. MZ twins are more alike than DZ twins in tests of motor skill (McNemar, 1933) and mechanical ability (Brody, 1937). Thus expressive movements, speech characteristics and preferred activities—all of which are closely related to personality—appear to be largely genetically determined.

Questionnaire tests of neurotic tendencies, interests, etc. (Carter, 1932, 1933; Holzinger, 1929) generally

show lower levels of correlation (*see* Table VIII.7), but such tests often lack reliability, and validity. On the basis of such studies alone one cannot justifiably conclude, as has sometimes been done, that personality characteristics are much less highly determined genetically than intelligence.

TABLE VIII.7
TWIN RESEARCH: RESULTS, EXPRESSED IN THE FORM OF CORRELATION COEFFICIENTS, OF SELECTED PSYCHOLOGICAL TESTS APPLIED TO MONOZYGOTIC AND DIZYGOTIC TWINS REARED TOGETHER

(For references *see* text)

Test	r_{MZ}	r_{DZ}
<i>Intelligence tests</i>		
Wingfield (National Intelligence Test and McCall's Multimental Scale)	0.90	0.57
Herrman and Hogben (Otis)	0.84	0.48
Newman, Freeman and Holzinger (Binet) . .	0.88	0.63
Blewett (factor score)	0.76	0.44
Eysenck (data of Blewett and McLeod) (factor score)	0.82	0.38
<i>Other psychological tests</i>		
Mechanical aptitude (Brody)	0.69	0.28
Motor skills (McNemar)	0.79	0.43
Bernreuter's neurotic inventory (Carter) . .	0.63	0.32
Woodworth-Matthews' neurotic tendencies (Holzinger)	0.56	0.37
Strong's vocational interests (Carter) . . .	0.50	0.28
Autonomic factor (Eysenck, data of Blewett and McLeod)	0.93	0.72
Neuroticism factor (Eysenck and Prell) . .	0.85	0.22
Extraversion factor (McLeod)	0.77	0.03
Extraversion factor (Eysenck, data of Blewett and McLeod)	0.50	—0.33

Besides self-ratings, the opinions of others have been used to investigate similarities and differences between twins. According to Lassen (1931) teachers' ratings on a large number of social and moral characteristics have much higher correlations between MZ than DZ pairs. This may have been influenced by a halo effect. Similarly H. E. Jones (1955) reports that parents more often perceive personality differences in the case of DZ than MZ twins. However, Jones considers that these opinions of the parents of the twins may have the effect of producing an environment in which greater similarities come to be expected of MZ than of DZ twins. This stereotyping process might, he thinks, be of importance in maintaining or increasing the similarity of twins in certain traits.

Instead of using a single test, Eysenck and Prell (1951) used a variety of tests of different kinds, all

purporting to discriminate between neurotic and normal subjects, and extracted the factor which they had in common. The tests were given to twenty-five pairs each of MZ and DZ twin schoolchildren and to a "criterion" group of children from a child guidance clinic. The score for the factor of neuroticism had a higher correlation between twins than the scores of any of the separate tests. r_{MZ} for factor score was 0.85, and r_{DZ} 0.22; h^2 was 0.82—even higher than h^2 for intelligence. The authors concluded that their factor of neuroticism was a biological reality and not just a statistical artefact, and that it was highly inheritable as a whole.

Two years later, Blewett (1953) repeated the experiment of Eysenck and Prell on a fresh sample of twins, using a largely different set of tests, but these did not intercorrelate in the expected way and no factor of neuroticism could be extracted. However, McLeod (1954) tested the same twins with tests designed to measure extraversion-introversion and found a very large difference between the two kinds of twin in their resemblance in factor score ($r_{MZ} = 0.77$, $r_{DZ} = 0.03$; $h^2 = 0.77$). Eysenck (1956) reanalysed the combined data of Blewett and McLeod and, in addition to factors for intelligence and autonomic function, extracted an extraversion factor which gave a r_{MZ} of +0.50 and a r_{DZ} of -0.33; the difference was significant at the 2 per cent level. The very low correlations between DZ twins in the study of McLeod and the negative one in that of Eysenck may possibly be attributable to the small size of the sample.

In 1953 Cattell devised an ingenious experimental design to analyse the contributions of heredity and environment, and of any correlation between them, to the variance of scores on personality tests. This makes use of (a) MZ twins in their own families, (b) siblings in their own families, (c) siblings, each member of a pair in a different family, (d) pairs of unrelated persons brought up in the same family, and (e) unrelated persons in different families. From their scores a series of equations can be solved for heredity and environment, both within and between families. Unlike other statistical methods hitherto proposed, such as Holzinger's h^2 , this multivariate design takes into account any correlation between the single variances. Two years later Cattell and his colleagues (1955) reported on the first attempt to apply this design to the scores of schoolchildren on twelve personality factors from his "Junior Personality Quiz." He was, however, unable to obtain a sufficient number of pairs under group (c) above. The results are rather difficult to interpret. However, Tender-mindedness, General Neuroticism and Somatic Anxiety were among those factors found to be determined predominantly by the environment. Cyclothymic factors

and General Intelligence were predominantly determined by heredity.

Although considerable advances have been made in methodology, it cannot yet be claimed that objective tests of personality have given consistent results when applied to problems of heredity.

DEVIATIONS OF PERSONALITY

The relevance that findings based on measured personality factors would have to the genetics of neurosis and psychopathic personality lies, of course, in the widely held view that these conditions consist for the most part of deviations along one or a number of different dimensions of personality. The problem can, however, be approached more directly, though not in such a quantitative way, by investigating along more traditional lines.

Besides the twin studies referred to on pages 323-330, there have been a number of family studies, in which workers have investigated the incidence of all kinds of psychiatric abnormality among the relatives of persons showing some particular deviation of personality: von Baeyer (1935) on the relatives of pathological liars and swindlers, Brown (1942) on the families of anxiety neurotics, hysterics and obsessionals Cohen *et al.* (1951) on "neurocirculatory asthenia," Edith Rüdin (1953) on obsessional neurotics, and Ljungberg (1957) on conversion hysteria. All of these workers have found an excess of psychiatric abnormality, compared with the general population, among the relatives of these people, but not always of specifically the same kind. Thus von Baeyer found among the relatives of his pathological liars no large absolute number of swindlers of a similar kind, but rather an excess of persons showing similar personality traits, i.e., an excess of extreme extraverts, of cyclothymics, and people with marked hysterical traits. Brown found, among the relatives of the anxiety neurotics, an excess of anxiety neurotics, but also an excess of hysterics and of emotionally unstable people. Such findings as these led Slater and Slater (1944) to postulate not only a multifactorial but also a multidimensional genetical basis for the so-called neurotic and psychopathic deviations of personality. The hypothesis enables one to understand, on the basis of a simple working model, such facts as the shading off of the neurotic or psychopathic into the normal, and the clinical finding that most patients show weaknesses or handicaps of personality of more than one kind. The point has been effectively made by Williams (1956) that, if we take the 95 per cent level as the line of demarcation between "normal" and "abnormal," only 60 per cent (0.95¹⁰) of people would be normal for all of ten characters, and less than 1 per cent for all of a hundred.

There is also a probability that specific genetic

factors may cause a deviation of personality not amounting to illness. Thus among the relatives of schizophrenics there is an excess of persons of schizoid personality, which might be explained if they were heterozygous for the hypothetical schizophrenic gene. A similar phenomenon may hold also in the families of manic-depressives. (Personality deviations may also arise from purely environmental causes of many kinds, from birth trauma and organic illness in childhood, to defects in upbringing and conditioning in the widest sense.)

Interesting studies of superior personalities and their families have recently been made by Juda (1953) and by Roe (1953). Roe studied sixty-four prominent American-born scientists and compared them with a control group of university faculty members of lesser distinction. As might have been expected, a combination of hereditary and environmental factors appeared to be responsible for the superiority of the *élite* group. Juda's material consisted of two hundred and ninety-four German-speaking men and women of the most outstanding achievement in the arts and sciences during the past three hundred years. Nearly all came from families with other signs of talent, and many were related to one another. The rate of mental abnormality in the relatives was raised by only a small amount; and though the incidence of abnormalities of personality among the subjects themselves was well above average expectations (about 20 per cent), yet one could still say that the great majority of them were healthy and normal. The view that practically all creative workers are psychopathic or insane is shown to be a travesty of the facts. Both Juda and Roe found an excess of first-born among their superior subjects.

PSYCHOSIS

We have already mentioned the hypothesis that a dominant gene with reduced manifestation plays an important part in the causation of *manic-depressive psychosis*. This theory, rather than one of multifactorial inheritance, is favoured by the fact that the tendency to endogenous mood swings seems to have a bimodal distribution. In the families of manic-depressives one rather frequently comes across persons who, though not necessarily psychotic, show marked depressive moods at times, or hypomanic phases, which occur spontaneously and without any clear environmental cause. Other members of the same families show no such tendency, and one can draw usually a fairly clear line between them. The presumption is that in those subject to endogenous mood swings, the temperamental deviation is attributable to the same gene as the psychosis, and that classification as a psychotic depends on the mood swing being long and severe enough to need psychiatric treatment.

Quite distinct, clinically, from the tendency to endogenous mood swings, is the tendency to over-react emotionally to strains and stresses of both a physical and psychological nature. The depression which may result is usually diagnosed as "reactive"; but some psychiatrists do not recognize the distinction between "reactive" and "endogenous."

It is probable that manic-depressive, or cyclothymic, disorders are not the only forms of affective psychosis which may have a hereditary basis. So-called involutional depression is probably a heterogeneous group of illnesses, including some manic-depressives, some schizophrenics, and perhaps also a nuclear group of a specific kind; this latter group would consist of people who fall insidiously ill on the basis of a rigid and obsessional, rather than a cyclothymic, personality. However, the most recent study of the genetics of involutional depression, that of Stenstedt (1959), failed to confirm this association between involutional depression and schizophrenia. While agreeing that involutional depression was aetiologically heterogeneous, environmental factors playing an important role in many cases, the results of his work were to support the older view that in so far as it was genetical it could not be distinguished from manic-depressive disorders. However, the milder (non-psychotic) cases did not differ aetiologically from severe (psychotic) depressions.

While there is a great deal of evidence from twin and family studies that hereditary factors are of considerable importance in *schizophrenia*, there is still no general agreement on the mode of inheritance. Kallmann (1938, 1946, 1950), who has done more on the subject than anyone else, postulates a recessive gene whose effects are influenced by modifying genes, but a dominant gene with reduced manifestation has its supporters (Böök, 1953; Koller, 1939). There may not be as much difference between these views as might at first appear. Kallmann supposes that there is some degree of manifestation in the heterozygote, e.g., as a schizoid personality; and this would bring the mode of inheritance near to an intermediate type.

In his study of a North Swedish population, Böök calculated that his data could be explained by a gene manifesting itself in all homozygotes and in about one in every five heterozygotes. This hypothesis has been further examined by Slater (1958); and it was shown that the principal data supplied by Kallmann and Elsässer were in conformity with a gene of this intermediate type. At a gene frequency of 0.015, with manifestation in 26 per cent of heterozygotes, the theoretical expectancies of schizophrenia in the sibs of schizophrenics, the children of one schizophrenic, the children of two schizophrenics, and in the children of cousins were, respectively, 0.144, 0.143, 0.396, and

0-008. The corresponding observational findings are 0-142 (Kallmann), 0-164 (Kallmann), 0-392 (Elsässer), and 0-011 (Nixon and Slater). On this basis, some 70 per cent of all persons carrying an adequate genetical predisposition to schizophrenia would not fall ill, leaving therefore a considerable margin for the operation of environmental factors. The fact that schizophrenia is a relatively common disease as well as a biologically malignant one could be accounted for on this theory if there was some degree of heterozygotic advantage.

This is probably not the only genetical model which could be constructed to account for the available data, but it supplies an adequate working hypothesis. Attempts to demonstrate genetical heterogeneity for schizophrenia have not been entirely convincing so far. It seems unlikely that there will be any decisive answer to the problem without advances in other fields, e.g. the biochemical basis of schizophrenia.

ORGANIC STATES AND EPILEPSY

Some forms of brain damage, including senile dementia and Huntington's chorea, are due very largely to the genetic constitution, and their psychological consequences depend closely on the extent of the brain damage. Genetical factors also play a part, but a more remote one, in the causation of arteriosclerotic dementia; they enter into the causes of arteriosclerosis, but other factors may determine how far the brain itself is damaged and hence how much psychological change there is. (Most brain tumours are non-genetical.) The psychological consequences of head injuries are of course primarily accounted for by the site and the amount of damage done; but brain injuries may also precipitate psychoses or bring out latent personality traits in predisposed persons.

One of the consequences of brain injury may be epilepsy, but in most epileptics no plausible external cause can be found. The genetical constitution is quite important in determining how easily a person develops epilepsy. This is probably a graded characteristic. The capacity to respond with a major convulsion to certain stimuli is universal in man, and this fact is made use of in the treatment of depression with E.C.T. But the threshold at which a fit occurs ranges from those who are most resistant down to those who suffer from "idiopathic" epilepsy. All investigations of the relatives of idiopathic epileptics have shown an increased incidence of epilepsy, and the genetical factor has also been demonstrated by twin studies. However, Ounsted (1955) has shown that the incidence of epilepsy in other members of the family is related to the nature of the fits; and the most trivial cases, such as infantile convulsions, often have the heaviest family loading. Ounsted found that 25 per cent of the sibs of the children who had had infantile convulsions had some form of convulsive disorder. When adult

epileptics are investigated (e.g., by Alström, 1950), lower rates for the incidence of epilepsy in sibs have been found, usually around 4 per cent.

Studies with the EEG by Lennox (1939) and others indicate that electrical patterns of brain activity have a genetical constitutional basis. Lennox found that there was a high incidence of *cerebral dysrhythmia* in the parents of epileptics, and he postulated that this was connected with the possession of a dominant gene. Epileptics would then be constitutional dysrhythmics, who had suffered in addition some environmentally caused trauma sufficient to bring on epilepsy. However, there is too much individual variation in brain-wave patterns, even when taken under standardized conditions, for dysrhythmia to be a satisfactory unitary concept; and abnormalities of the pattern may also take a great number of different forms. The best measure of instability of brain physiology is obtained by submitting the subject to a graduated increasing dosage of a convulsant drug, given by intravenous injection; the level of dosage at which, first abnormalities in the EEG, and finally a convulsion, occur then becomes the required measure. Individual variation in this respect shows every sign of being a graded character, its genetical basis being then of a probably multifactorial kind.

CONCLUSION

In this chapter we have presented the genetical contribution to the study of abnormal psychology in very largely psychiatric terms. There are of course abundant reasons for this, into which we need not enter. One of them has been the fact that most of the genetical work on psychological abnormalities has been concerned with psychiatric syndromes, rather than with psychological concepts, such as perception, memory, emotion and learning. It is probable that those who are concerned with human genetics in the first place will continue to work along the same lines, for, as must have been seen, there are many pressing unsolved problems. Genetics, however, has another contribution to make, that of providing the framework for primarily psychological investigation, such as is seen in the work of Eysenck and his associates.

We began the chapter by asking in what sense and to what extent can physical heredity be offered as an explanation of psychological abnormality, or rather of various specific kinds of abnormality, for there can be no general answer. From the discussion which followed it can perhaps be seen that genetical studies try to answer three different but related kinds of question: the mode of inheritance (formal genetics), how the genes manifest themselves (developmental genetics), the relative share of heredity and environment (analysis of variance). The importance we

attribute to heredity depends on which question we are most interested in, and this in turn depends on the nature of the condition under investigation and the point of view of the inquirer.

The first of these questions will be asked most often of specific non-normally distributed conditions. Ideally, the answer should be given in Mendelian terms, and with some estimate of the frequency and the distribution of the gene in the population. The influence of factors other than the specific gene, both those of a genetical and environmental kind, will appear in reduction of the manifestation rate or variabilities in expression. The greater the variability of expression, the more difficult the analysis becomes; and the lower the manifestation rate, the less important and less useful. Answers will be interesting to the geneticist, and of relevance to the eugenist.

The second question relates to the mode of interaction between heredity and environment. The work involved stretches from biochemical investigations on the action of single abnormal genes, over such work as Grüneberg's on embryo rats, to social and psychological studies of twins. The results are of the greatest interest to the practical clinician; they may affect his work, from the theoretical side of the classification of diseases to the purely practical aspect of treatment. Abnormalities due to single-gene differences will occupy pride of place; but deviations from the norm caused multifactorially will become increasingly accessible.

The third question is one which has dominated psychologists, particularly educational psychologists, in the past, as it has considerable social significance. Its importance, however, will diminish as our capacity to answer the first two questions improves. It has been, and still is, a battleground for debate, not always either dispassionate or sensible. The question is still worth asking about conditions which are graded in degree, can be measured with reasonable reliability and accuracy, and are universally distributed; and the answers obtained may be very important, though only in a limited field. They also suffer from being entirely provisional. As we have already mentioned, they can apply only to a limited population, extrapolation being more than usually dangerous, and they are rendered obsolete at once by any large and general change on either the genetical or environmental side. It is probable that, as our knowledge increases, we shall turn more and more in other directions.

 SORSBY, A. (Ed.) *Clinical Genetics* (London, Butterworth, 1953 (580 pp.)).
 Includes chapters on: the detection of carriers (Neel); polygenic inheritance (Mather); biometric evaluation of findings (Dahlberg); the inheritance of morphological and physiological traits (Tanner); diseases of the nervous system (Pratt); oligophrenia (Book); psychiatry (Slater); the sense organs (Sorsby and Lindenov).
 STERN, C., *Principles of Human Genetics* (San Francisco, Freeman, 1950 (617 pp.)).

Psychiatry

- MAYER-GROSS, W., SLATER, E. and ROTH, M., *Clinical Psychiatry* (London, Cassell, 1954 (652 pp.)).
 PENROSE, L. S., *The Biology of Mental Defect* (London, Sidgwick & Jackson, 1949 (285 pp.) 2nd ed., 1954).

Genetics in Psychiatry and Psychology

(a) Books and Symposia

- CONGRÈS INTERNATIONAL DE PSYCHIATRIE, PARIS, 1950.
 Rapports: VI. *Généétique et Eugénique* (Paris, Hermann, 1950 (192 pp.)).
 Reports on: the genetics of the psychoses (Kallmann); research methods (Penrose); the genetics of oligophrenia (Fraser Roberts); the genetical aspects of personality and neurosis (Slater); population studies in psychiatry (Stromgren).
 HOOKER, D. and HARE, C. C. (Eds.) *Genetics and the Inheritance of Integrated Neurological and Psychiatric Patterns*, Research Publications, Association for Research in Nervous and Mental Disease, Vol. 33 (Baltimore, Williams & Wilkins; London, Baillière, Tindall & Cox, 1954 (425 pp.)).
 Includes chapters on: the principles of human genetics (David and Snyder); the inherited and acquired components of behaviour (Anastasi); the development of behaviour patterns (Gesell); the inheritance of intelligence (Thompson); personality development of the child (Senn); phenylketonuria (Jervis); epileptic twins (Lennox and Jolly); the familial occurrence of migraine (Goodell *et al.*); the genetics of psychotic behaviour patterns (Kallmann); genetic aspects of adaptability (Glass); the clinical applications of genetics (Neel).
 KALLMANN, F. J., *Heredity in Health and Mental Disorder*

- (London, Chapman & Hall; New York, Norton, 1953 (315 pp.)).
- Based on the 19th Thomas W. Salmon Lectures: contains the most complete and recent account of Kallmann's comparative twin studies.
- NATIONAL SOCIETY FOR THE STUDY OF EDUCATION. *Twenty-seventh Yearbook*, 1928. Part I: Nature and Nurture, their influence upon intelligence (460 pp.). Papers on: family resemblance in intelligence (Thorndike and Jones); the intelligence of foster children (Burks; Freeman *et al.*). (Bloomington, Public School Publishing Co.)
- NATIONAL SOCIETY FOR THE STUDY OF EDUCATION. *Thirty-ninth Yearbook*, 1940. Intelligence, its Nature and Nurture. Part I: Comparative and critical Exposition (471 pp.). Reviews by: Carmichael, Carter, Cattell, Freeman, Goodenough, Terman, Wellman and others. Part II: Original Studies and Experiments (409 pp.) (Bloomington, Public School Publishing Co.).
- Recent Progress in Genetics and its Implications for Psychiatric Theory, *Amer. J. Psychiat.*, **113**, 481-505 (1956). (Papers by: Bentley Glass, Franz Kallmann, H. J. Muller and Linus Pauling).
- WOODWORTH, R. S., *Heredity and Environment* (Bulletin 47, Social Science Research Council, New York, 1941 (96 pp.)).
- (b) *Critical Reviews*
- COWIE, V. and SLATER, E., Psychiatric genetics, in *Recent Progress in Psychiatry*, Ed. G. W. T. H. Fleming (London, Churchill, 1957 (pp. 1-53)).
- SLATER, E., Genetics in psychiatry, *J. Ment. Sci.*, **90**, 17-35 (1944).
- SLATER, E., Psychiatric genetics, in *Recent Progress in Psychiatry*, Ed. G. W. T. H. Fleming (London, Churchill, 1950 (pp. 1-25)).
- (c) *Journals and Monographs*
- The following genetical journals sometimes contain papers relevant to psychology—
- Acta Genetica et Statistica Medica* (Basle and New York, Karger).
- Acta Genetica Medicae et Gemellologiae* (Rome, Instituto Gregorio Mendel).
- Acta Psychiatrica et Neurologica Scandinavica* (Supplements) (Copenhagen, Munksgaard).
- American Journal of Human Genetics* (Baltimore, American Society of Human Genetics).
- Annals of Human Genetics* (formerly *Annals of Eugenics*) (London, Cambridge Univ. Press).
- Eugenics Quarterly* (New York, American Eugenics Society).
- Eugenics Review* (London, Cassell).
- Opera ex Domo Biologiae Hereditariae Humanae Universitatis Hafniensis* (Copenhagen, Munksgaard).
- ALSTRÖM, C. H., A study of epilepsy in its clinical, social and genetic aspects, *Acta psychiat., Kbh.*, Suppl. 63 (1950).

CHAPTER 9

Constitutional Factors and Abnormal Behaviour

LINFORD REES

THE study of human constitution has for one of its major objectives the discovery of stable organic correlations (integrated biological relations between the morphological, psychological and pathological characteristics of the individual) and eventually the precise numerical measurement of such correlations (Pearl and Ciocco, 1934).

The term constitution is variously used and most frequently in the limited sense of susceptibility to disease. In this work the term is used in its wider connotation and refers to the sum total of the morphological, psychological and physiological characters of an individual, all being mainly determined by heredity but influenced, in varying degrees, by environmental factors.

Physique lends itself more readily to exact measurement than other constitutional attributes, and provides a convenient starting point for the study of correlations between the various aspects of human constitution.

There is an infinite choice of morphological and other constitutional attributes for the study of human constitution. Attributes which show marked variability between individuals and relative constancy within the individual are more likely to be the most useful and relevant for human constitutional research. The choice of variable will ultimately be determined by practical results, viz. its usefulness, fruitfulness and validity in studying constitutional correlates. The concept of human constitution connotes predominant genetic determination and the relative constancy of constitutional attributes within the individual. Observable and measurable morphological characteristics are conveniently referred to as the morphophenotype. The morphophenotype is the resultant of the interaction of the morphogenotype (i.e. the sum total of the genetically determined morphological characteristics) and environmental influences.

The various aspects of human constitution which may be investigated can be classified into—

1. *Morphological.* Among various morphological characteristics studied in human constitutional research are general bodily configuration (physical type, bodily *habitus*, somatotype); body size; the distribution and relative development of tissue components, e.g. muscle, fat, skeletal and connective tissue; relative development of various physical attributes, e.g. disharmonious growth (dysplasia), the relative development of masculine and feminine characteristics (androgyny, gynandromorphy), etc.

2. *Physiological.* Particularly relevant in constitutional studies are the functional characteristics of the autonomic, central and peripheral nervous systems; cardiovascular and other visceral functions; anabolic-catabolic processes; biochemical characteristics; endocrine balance, etc.

3. *Psychological.* Aspects of human constitution include personality in its manifold aspects, temperament, character, intelligence, perceptive characteristics, psychomotor functions, etc.

4. *Immunological.* This classification includes relationships between various constitutional attributes and disease susceptibility, including physical illnesses, psychiatric and psychosomatic disorders.

The origin of concepts regarding possible relationships between physical and psychological characteristics and predisposition to diseases is rooted in antiquity and the present status of constitutional research can best be considered against the background of its historical development.

Historical Development of Concepts Relating Physical and Psychological Characteristics

The tendency to classify one's fellow beings into types according to physical characteristics is deep-rooted in human nature and has been carried out from ancient times.

Classification into types serves to bring the chaos of manifold individual differences into some degree of order.

The ancient Hindus classified men, according to physical and behavioural characteristics, into types designated the hare, the bull and the horse, and women, into types referred to as the mare, the elephant and the deer.

Physicians of ancient Graeco-Roman medicine described a number of different physical types with alleged specific susceptibility to certain diseases. Other writers attempted to correlate external lineaments of the body with mental and moral qualities.

The tendency to correlate physical and mental attributes can be described historically, in three main fields—

(a) Social-cultural notions of stereotypes, as exemplified by quotations from the literature.

(b) Medical. The attempt to discover correlations between various types of somatic *habitus*, temperament and susceptibility to diseases.

(c) Physiognomy, or the study of man's external lineaments, as a clue to his mental and moral qualities.

POPULAR NOTIONS OF PHYSICAL TYPE CORRELATES

In literature we find popular notions dating from antiquity that persons of certain physical types are associated with characteristic personality, character or degree of intelligence. In Plutarch's *Lives* (Chap. 62, Sect. 5) Julius Caesar exclaims: "I am not much in fear of those fat, sleek fellows but rather of those pale, thin ones." He refers to Anthony and Dolabella as the fat ones and to Brutus and Cassius as the thin ones. Shakespeare refers to relationships between physique and personality in a number of plays, the best example probably being in Caesar's remarks to Anthony (*Julius Caesar*, I, ii, 192)—

Let me have men about me that are fat;
Sleek-headed men and such as sleep o' nights.
Yond' Cassius has a lean and hungry look;
He thinks too much: such men are dangerous. . . .
Would he be fatter! but I fear him not:
Yet if my name were liable to fear, I do not know the
man I should avoid
So soon as that spare Cassius.

The idea of a relationship between physique and intelligence is expressed in the old Italian proverb *Capo grasso, cervello magro* (Fat heads, lean brains); in an old Greek proverb which states: "A gross belly does not produce a refined mind" and in Shakespeare's *Love's Labour's Lost* (I, i, 26)—

Fat paunches have lean pates, and dainty bits
Make rich the ribs but bankrupt quite the wits

The good humoured jollity and physical proportions of Falstaff are well known. Finally, the old English apothegm, "Fat and merry, lean and sad," may be quoted as it describes succinctly the popular notion of association between personality and physique.

Similarly, we can trace the concepts of the relationship between physical and temperamental characteristics right back to the time of the ancient Greek scholars and physicians. It is possible, as described by Ciocco (1936), to trace two parallel lines of development in the study of relationship between physical and mental attributes. The first is concerned with the humoral theories of the early Graeco-Roman writers, and the second is the science of physiognomy, founded by Aristotle.

HUMORAL CONCEPTS OF CONSTITUTION

Physical characteristics played a prominent part in the humoral theories of ancient Graeco-Roman medicine. Hippocrates (460–377 B.C.) thought sound health to be due to an optimum mixture of humours and disease to a disturbance of this relationship.

The humours were four in number, because, according to Empedocles and Pythagoras, there were four primary elements from which all substances were constituted, namely fire, water, earth and air, to which corresponded the four humours, blood, lymph and black and yellow bile. Galen (c. A.D. 129–199) gave detailed descriptions of nine temperamental types, which were considered to be determined by various mixtures of the humours. The various temperamental types were characterized by variations in the character of skin, hair, fat, skeleton, muscle, shape of chest, etc. The perfect temperament was characterized by physical symmetry. The Galenic doctrine of temperaments was, in fact, a general theory of disease causation as well as an attempt to explain individual differences in behaviour. Galen's teaching dominated medical thought and practice for many centuries. It was reproduced by Sir Thomas Elyot in 1534 in his book *Castell of Helth*. Stahl (1660–1734), being influenced by the then recent discovery of the circulation of the blood by Harvey, modified Galen's doctrine and attributed temperamental differences to the passage of various humours through channels of varying size. The fourfold classification of temperaments into sanguine, phlegmatic, choleric and melancholic types was reproduced in the eighteenth century, by Thomas Laycock, Professor at Edinburgh.

Parallel to the study of constitution in relation to disease was the study of physiognomy.

DEVELOPMENT OF THE STUDY OF PHYSIOGNOMY

Aristotle (384–322 B.C.) is regarded as the founder of the subject physiognomy, which attempted to justify popular and traditional concepts relating man's external lineaments with his mental and moral qualities. He published his beliefs in a book entitled *Physiognomonica*, in which he stated that the mental character is conditioned by the state of the body.

The study of physiognomy was carried on, as described by Ciocco (1936), in a similar fashion by Polemonis, a Greek writer of the third century A.D., and Adamantius, a Jewish physician of the fourth century A.D.

Della Porta (1536–1615) published a book *De humana physiognomonica*, in which he reported many facial characteristics which were alleged to accompany different moral and intellectual traits. This work is mostly speculation and based on a minimum of observation, as is Lavater's book on physiognomy (1841).

In the late eighteenth and early nineteenth centuries, the study of physiognomy was deflected by the work of Combe, Gall and Spurzheim (1809) into the now discredited science of phrenology, and later in the nineteenth century by the work of Lombroso (1891, 1911), who founded the doctrine of criminal anthropology, which postulated that the criminal as found in prison was an atavistic anomaly presenting morbid physical stigmata.

MODERN DEVELOPMENT OF KNOWLEDGE OF HUMAN CONSTITUTION

No significant progress was made in the study of the relationship between physical constitution, character and susceptibility to disease from the time of Hippocrates and Galen until the late nineteenth century, when Beneke (1878), a pathologist of Marburg, published data on the measurements of various internal organs, and the variations in size associated with age, disease and physical type. He described two main physical types: (1) the scrofulous-phthisical and (2) the rachitic-carcinomatous, which roughly correspond to the modern distinction of the narrow and the broad types of body build.

Working round about the same time, was an Italian physician, Di Giovanni (1880) who made an extensive study of the relationship between physical constitution and susceptibility to diseases and who may be regarded as the founder of clinical anthropometry. He, however, went to the extreme of trying to prove that the cause of the special morbidity of an organ resided in its disproportionate development relative to that of other organs. He classified individuals by means of combinations of certain physical characteristics. His first and third combinations corresponded to the modern narrow and broad types. The Italian school of clinical anthropology, founded by Di Giovanni, was continued by Viola (1925 and 1932), who made extensive investigations into physical characteristics of the population of Northern Italy. He concluded that different physical types were due to differences in the relative development of the trunk and limbs. Viola's index has trunk volume (eight measurements) as the denominator and the length of the arm and leg

as the numerator. He recognized three morphological types—

1. the megalosplanchnic, characterized by a preponderance of the vegetative or digestive system, having a large trunk and short limbs;
2. the microsplanchnic, characterized by preponderance of the limbs over the vegetative or digestive system, having a small trunk and long limbs;
3. the normosplanchnic, which is midway between (1) and (2), having the harmonious relationship of trunk and limb.

Other workers of the Italian school included M. Boldrini (1931, 1935), who corroborated Viola's thesis of the fundamental relationship between trunk volume and limb length for discriminating physical types. He demonstrated statistically that chest circumference and stature could be substituted for the trunk volume and limb value of Viola's unwieldy index.

Using an index consisting of $\frac{\text{circumference}}{\text{stature}}$ he found

that brevity types, corresponding to the megalosplanchnic type, tended to have numerous progeny, whereas longity types, corresponding to the microsplanchnic type, tended to have a higher age of death and a smaller number of progeny.

Boldrini's system was statistically strong, but anatomically weak, whereas Viola's system was strong anatomically, but weak statistically.

The Work of Kretschmer

The modern revival of interest in the relationship between physical constitution, temperament, personality and psychiatric disorders was greatly stimulated by the work of Ernst Kretschmer, who, in 1921, published his book entitled *Körperbau und Charakter*.

Starting with the study of psychotic and potentially psychotic patients, he described, using a limited number of physical measurements, four main types of physique—

1. the asthenic or leptosomatic type, characterized by deficiency in thickness in all parts of the body. Length tends to preponderate in comparison with breadth and circumferential measurements;
2. the athletic type with a strong development of skeletal and muscular systems. The shoulders are wide, the chest is well developed and the trunk tapers in its lower part;
3. pyknic or pyknosomatic type is characterized by pronounced development of the body cavities and a tendency to increased fat deposition on the trunk. The extremities are short relative to circumferential measurements. The feet and hands tend to be broad and well upholstered with fat;

4. dysplastic group, which includes certain marked dysglandular syndromes.

He studied the distribution of these types in eighty-five manic-depressive patients and one hundred and seventy-five schizophrenics and concluded—

1. that there was a clear biological affinity between the psychic disposition of manic-depressives and the pyknic type of body build;

2. that schizophrenics exhibit, with many varieties of crossing and blending, the characteristic features of a diversity of physical types, the most common of which, are the leptosomatic, asthenic and certain types of dysplasia (viz. certain varieties of eunuchoid, polyglandular obesity, infantilistic and hypoplastic physiques);

3. that there was a weak affinity between schizophrenia and pyknic body build and likewise between manic-depressive psychosis and leptosomatic, athletic and dysplastic types of body build.

Kretschmer extended his theory from the realm of psychotic types to normal personality types. He traced a gradation of temperamental characteristics from the pathological schizophrenic patient through schizoid psychopathy to the well-adjusted schizothymic personality. Likewise he traced a gradation of characteristics from manic-depressives through cycloid psychopathy, to normal well-adjusted cyclothymic personality. He contended that schizoid psychopaths and schizothymes tend to have leptosomatic, athletic and certain types of dysplastic physique and that cycloid psychopaths and cyclothymes tended to have a pyknic type of physique.

The work of Kretschmer must be accorded due importance, not only because he elucidated relationships between physical types and certain psychotic illnesses, but because of the tremendous amount of research which was stimulated by his theory. The value of his work was limited because of certain methodological difficulties, for example, his description of types was to a large extent based on clinical impression and only to a very limited degree defined by anthropometric measurements and indices. His classification tended to emphasize the existence of physical types as discrete and independent entities, although he does stress that the types described by him should be regarded as focal points around which a number of variations are distributed.

A large number of workers subjected Kretschmer's hypothesis to experimental investigation. Some investigators were unable to support Kretschmer's hypothesis from their findings, others only in part and some were able to give strong support to the theory; these will be discussed more fully later.

Much of the work that followed the publication of

Kretschmer's (1921) theory was handicapped because the variations in body build in the normal population had not been ascertained by satisfactory objective inductive methods. Knowledge regarding factors underlying such variations was lacking and indices of body build, which were available, were not based on an inductive approach designed to determine which measurements in fact were likely to discriminate physical types.

Survey of Classifications of Physical Types

A large variety of typological classifications of physique have appeared since Hippocrates delineated the *habitus pithicus* and the *habitus apoplecticus*.

A list of such classifications is given in Table IX.1.

The basis used for various classifications is diverse, varying from general body shape and other morphological characteristics to theories based on alleged physiological, immunological, dietetic and developmental features.

It is noteworthy that the majority of authors, many unknown to each other, have described more or less corresponding physical types as shown in the respective columns of Table IX.1. Generally a dichotomy of physique is described with contrasting antithetical types in columns 1 and 3, with a third type in some classifications.

The theory of physical types as disparate and mutually exclusive categories of body build has had to be abandoned in the light of more recent research and is now replaced by the concept of a continuous variation in body build (Rees, 1943).

During recent years a number of new techniques have been applied to the study of body build. These include—

1. factorial analysis and other statistical procedures for investigating variations in body build;
2. Sheldon's system of somatypes;
3. Lindegard's method;
4. miscellaneous techniques such as analysis of tissue components, body disproportions, androgyny, etc.

Factorial Analysis of Human Physique

Until comparatively recently, constitutional research has been severely handicapped by the lack of reliable data concerning the variations in physique in the normal population and a lack of effective and economical description.

The problem was to develop a method which could deal inductively with the observed variations in physical dimensions, and which did not depend on preconceived ideas regarding the nature of the variations of body build and their determinants.

The technique of factorial analysis, which had proved fruitful in the study of intelligence, provided a

TABLE IX.1
COMPARISON OF CLASSIFICATION OF PHYSICAL TYPES

	1	2	3
Hippocrates (460-400 B.C.)	<i>H. apoplecticus</i>	—	<i>H. phthisicus</i>
Rostan (1828)	Digestive	Muscular	Respiratory-cerebral
Beneke (1876)	Rachitic	Carcinomatous	Scrofulous-phthisical
di Giovanni (1880)	3rd Comb.	2nd Comb.	1st Comb.
Manouvrier (1902)	Brachyskeletal	Mesoskeletal	Macroskeletal
Virenius (1904)	Connective	Muscular	Epithelial
Stiller (1907)	—	Hypertonic	Atonic

relatively objective and inductive method of elucidating the variations in body build and their description in the most economical way.

Factorial analysis is concerned with the resolution of a set of variables in terms of a smaller number of categories or factors. Essentially it is a method which reduces a large number of correlations or covariations between variables to a small number of factors accounting for the correlations or covariations.

Factorial analysis is of particular advantage in the study of human physique as it provides a holistic representation of the human body far more comprehensive than that given by anthropometric measurements alone. Factorial analysis may be applied to the study of physique in two distinct ways, i.e. either applied to traits (anthropometric measurements) or to persons.

The majority of factorial studies on physique deal with traits as these studies provide an inductive method of ascertaining the nature of variations in physique. Factorial analysis of persons instead of traits provides, as indicated by Burt (1943), a method of determining how true an individual is to a particular type. It involves the specification of the type in question by a set of representative measurements expressed in standard measure. The correlation of a given individual with the standard pattern indicates how nearly he approximates to a perfect representative of the type.

The steps undertaken in the factorial analysis of anthropometric measurements are—

1. The calculation of correlations or covariations between all measurements for the entire group giving a matrix of correlations or covariations.

2. Determining the factors underlying the observed correlations or covariations and removing the effect of each factor from the matrix before extracting the next factor; this process is repeated until the residual correlations are not significant statistically.

There are a number of different techniques of factorial analysis but, basically, each is concerned with analysing correlations or covariations in terms of factors which may refer—

1. to all the correlations or covariations in the matrix, i.e. general factors;
2. some of the correlations or covariations only, i.e. group factors;
3. specific or error factors which relate to separate measurements.

In the factorial methods usually employed in Great Britain, the factors extracted are independent or uncorrelated and are designated orthogonal factors.

Some factorial techniques involve rotation of factors in an attempt to get the best descriptions of groups of correlations, thus providing oblique or correlated factors.

The most frequently used factorial procedure is to extract a general factor first and then group factors relating to the shape of the body as a whole or of its constituent parts. Factorial analysis, whichever technique is used, provides a means of classifying body build with the fewest differentia covering the largest number of anthropometric data. The results of factorial analysis of physique also tell us which measurements help to discriminate and measure physical types. These may be combined in the form of a regression equation of weighted measurements, or in the form of suitably constructed ratios as indices of body build.

Factorial analysis was first applied to the study of physique by Spearman (1927); it was later employed by Cyril Burt (1938) and subsequently by Cohen

(1938, 1940, 1941) and Hammond (1942); there are more recent papers by Burt (1947, 1947, 1950, 1950), and by Burt and Banks (1947).

A description will be given of factorial studies of physique in adult men carried out by Rees and Eysenck (1945), and in adult women by Rees (1950) and the findings will be discussed in relation to those of

It was found that all the correlation coefficients between physical measurements were positive, indicating the existence of a general factor. A factorial analysis was carried out by Burt's (1940) summation method. Two main factors were extracted. The first factor, which had positive saturations throughout, contributed 34 per cent of the variance. The second factor was bipolar, having positive saturations with length measurements and negative saturations with breadth and circumferential measurements. This was clearly a factor of physical type, differentiating the *linear type* of physique at one extreme preponderating in length measurements in comparison with breadth and circumferential measurements, and a *broad type* at the other extreme, preponderating in breadth, width and circumferential measurements relative to length.

The factor saturations of body measurements are shown diagrammatically in Fig. 9.1.

A similar study was carried out by Rees (1950) on a group of two hundred female members of the Armed Forces suffering from neurosis, successively admitted to Mill Hill Emergency Hospital. The measurements taken in this group included stature, suprasternal height, symphysis height, breadth and length of skull, biacromial diameter, transverse chest diameter, sagittal chest diameter, bicristal diameter, length of sternum, length of arm, chest circumference at full inspiration and full expiration, hip circumference and weight.

Each of the fifteen variables was correlated with the others and the matrix of intercorrelation was analysed by Burt's (1940) summation method. Again it was found that all the measurements were positively correlated, indicating the existence of a general factor. When the effect of the general factor was removed, it was found that the residual coefficients were significant and varied from -0.33 to $+0.59$. The second factor extracted was bipolar having positive saturations for length measurements and negative saturations for breadth, width and circumferential measurements. This factor, as in the male group, accounts for the existence of two antithetical types of bodily architecture, viz. the narrow, linear or leptomorphic type at one extreme and its antithesis, the broad, lateral or euryomorphic type at the other.

The saturations of anthropometric measurements with the general and type factor in women are shown in Fig. 9.2.

These findings derived from factorial analysis of physique in British adult men and women are supported by a large number of other workers using factorial methods in groups of different ages, racial composition and socioeconomic status.

It was strikingly shown by Burt (1947), from an anthropometric study of 30,000 men of the Royal Air

FIG. 9.1. SATURATION OF ANTHROPOMETRIC MEASUREMENTS WITH GENERAL AND TYPE FACTORS, MEN

a number of other workers who have employed factorial methods.

Some of the results are shown in Table IX.2 and will be referred to later.

FACTORIAL STUDIES OF PHYSIQUE IN ADULTS

Rees and Eysenck (1945) calculated the intercorrelations of eighteen variables (age and seventeen body measurements) for a group of two hundred soldiers successively admitted to Mill Hill Emergency Hospital. The measurements utilized in the study were taken according to the standardized procedures described by Hrdlicka (1939), Martin (1928) and Wilder (1920), and included stature, suprasternal height, symphysis height, breadth and length of skull, biacromial diameter, transverse chest diameter, sagittal chest diameter, bicristal diameter, trunk length, sternal length, arm length to radial styloid, arm length to tip of medius, chest circumference at inspiration, chest circumference at expiration, hip circumference and weight.

Force, that in almost every age group and nationality the same two main factors emerged. Burt (1938) in his pioneering paper, describing factorial analysis of physical measurements in groups of British children and adults, also elicited a well-marked general factor and factors making for disproportionate growth in length, on the one extreme, and breadth, thickness, girth and weight on the other extreme.

Similar factors have been found from factorial studies on groups of different racial composition, e.g. Cohen (1941), in a group of one hundred Jewish patients in a mental hospital, Hammond (1942) in a group of one hundred adult Irishmen, and Burt (1944) in groups of young British and American men.

Thurston (1946) re-analysed data provided by Hammond (1942) consisting of twelve body measurements in a group of adult Irish males. He considered that there were four primary factors, two of these concerned with size and the other two concerned with length and breadth measurements, viz. (1) head size, (2) bone length, (3) transverse girth dimensions, and (4) a factor considered to be related to the size of the extremities.

The factors elicited from factorial analysis of body measurements will, of course, depend on the number and selection of the original measurements used. For example, Howells (1951) carried out a factorial analysis of physical measurements in one hundred and fifty-three university students. The data included a large number of head and face dimensions. There were three limb measurements and three facial length measurements. Howells elicited factors for limb and facial length and concluded that the factors extracted probably depended more on the measurements chosen than on growth patterns. He elicited, in all, seven factors, which he interpreted as relating to general body size, long bone length, cranial size, brain size, lateral facial cranial development, face length and ear size. These can be grouped into four size factors, two length factors and a breadth factor. Heath (1952) carried out a second order factorial analysis on twenty-nine measurements obtained on 4,128 women, taken in a study for women's clothing size standards. She extracted five first order factors, which were interpreted as length of bones, cancellous bone size, lower body girth, girth of extremities and upper body girth. Second-order factors were closely related to the usual length and breadth factors and the similarity between this solution and that obtained by the results of Rees and Eysenck (1945) and Rees (1950) was pointed out by Eysenck (1953).

Moore and Hsu (1946) carried out a factorial analysis of thirty-one measurements of head and body in a group of psychotic patients and found a general size factor; a factor of leptosomia, shown particularly in the length of hands, face, nose, long bones of the

limbs and stature; a factor of girth, or lateral type of body build, shown in chest, waist measurements and breadth of face; a factor of robustness, shown in forearm circumference, calf circumference and thickness of the neck. These can be grouped into a general

FIG. 9.2. SATURATION OF ANTHROPOMETRIC MEASUREMENTS WITH GENERAL AND TYPE FACTORS IN TWO HUNDRED WOMEN

size factor and a bipolar factor for leptosomia *v.* lateral and circumferential measurements.

FACTORIAL STUDIES OF PHYSIQUE IN CHILDREN AND ADOLESCENTS

The question arises whether the factors of physique elicited in adults are also found during the growth period of childhood and adolescence.

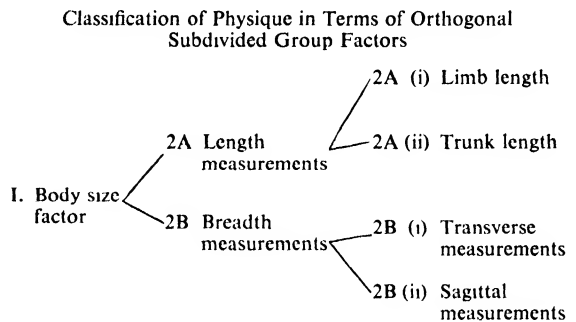

Carter and Krause (1936) analysed data provided

by Bakwen and Bakwen (1929) on neonates. A factorial analysis was carried out on groups of newborn babies, six hundred and eight male and six hundred and nine female. In both groups the results provided strong evidence of a general factor of size, the other factors elicited being difficult to characterize. Marshall (1936) factor-analysed eighteen measurements taken on children ranging in age from birth to 6 years. He considered that there was evidence for four group factors, one of which was identified with subcutaneous fatty tissue roughly corresponding to our general factor, but the other three group factors were difficult to characterize. Hammond (1957) reported factorial studies of physique in children ranging in age from birth to 18 years. In addition to his own data he used, for comparison, data obtained from Carter and Krause's (1936) analysis of the Bakwen's data and that provided from Low's (1952) Aberdeen study. In all age groups both in boys and girls, he found evidence of a general factor and a type factor which differentiated between the growth of long bones on the one hand and breadth of trunk and limbs on the other. He found, in addition, evidence of two subgroups corresponding to limb-breadth development and trunk-breadth development, which were related to some extent. Macloy (1940) carried out a factorial analysis on nineteen measurements on groups of boys and girls ranging in age from infancy to adult life. The first factor extracted was interpreted as being concerned with the development of fat and subcutaneous tissue. The second factor was one of linearity and the third was described as a cross-section type factor having saturations with girth, width and depth measurements. The second and third factors could be regarded as the opposite manifestations of a bipolar factor. The fourth factor extracted could not be clearly identified, but was most prominently related to chest measurements and shoulder width. Mullen (1940) studied groups of girls between 7 and 17 years of age and carried out a factorial analysis of anthropometric measurements in each age group. She found a general factor of size and two group factors, one being concerned with length and the other related to weight, bi-iliac width, bitrochanteric diameter, chest girth, chest width and chest depth.

Rees (1950) found that the results obtained by Mullen (1940) in American girls corresponded closely with the results of his investigation of two hundred adult British women. For example, there was a correlation of + 0.64 between the first factor saturation of the traits in Mullen's groups and Rees's group (Rees, 1950).

Burt (1949) gave further results derived from factorial analysis of four hundred and fifty-seven boys aged 12-13 years. The correlations between physical measurements were first analysed by the method of

simple summation and subsequently by the method of subdivided factors. The results of analysis involving subdivided factors indicated that the leptomorphic factor had two subfactors, one for limb length and the other for trunk length, and the pyknic factor had two subfactors, one for transverse measurements and the other for sagittal measurements.

When it is considered that the various factorial studies of physique have differed not only in factorial method but in selection of measurements, and have dealt with groups differing in age, sex and racial status, there is a noteworthy consistency in the results. When marked differences occur in results they may be accounted for by: (1) particular choice of anthropometric measurements (e.g. Howells, 1951), (2) the factorial technique used, or (3) the interpretations of the factors extracted.

It is agreed with Hammond (1957) that the most direct method of analysis is that of extracting a general factor and then bipolar contrasting factors. Group factors need only be invoked if this method proves to be inadequate to express the relations satisfactorily, as for example, when there is evidence of an odd number of groups, or when relationships appear to apply to a small part of the correlation matrix.

Accurate comparison of the results of different workers is only possible if the body measurements are the same. Alternatively the analysis must be confined to those measurements which are common to the respective groups. This requirement would involve re-analysis from the correlation stage and has the twofold disadvantage of being laborious and limiting the data eligible for comparison.

It should be remembered that the factors elicited by factorial analysis are primarily statistical abstractions and further research will be needed to ascertain their relationship to genetic factors and growth processes and to endocrine, metabolic or other biochemical processes.

The importance and possible biological significance of the general and type factors are attested by their discovery at all ages during the growth period and in

adult life, in each sex and also in different racial and social-cultural groups. Similar factors have been found in the animal kingdom, e.g. factorial analysis of physique of cows (Tanner and Burt, 1954), rabbits (Tanner and Sawin, 1953), and rats (Watson, 1956). The operation of the general and type factors in human physique is strikingly similar to the differential growth ratios determining body forms in the animal kingdom described by Huxley (1932).

INDICES FOR THE ASSESSMENT OF BODY BUILD DERIVED FROM FACTORIAL STUDIES

The results obtained from factorial analysis permit improvements to be made in the construction of indices for assessing body build. When the type factor has been isolated, it is possible to ascertain which measurements are correlated most highly with it and are therefore the ones most likely to be useful in the discrimination of physical types. There are a number of possible ways in which such information might be used to construct indices of body build. Undoubtedly, the best measure of body type would be given by a regression equation using body measurements as terms, weighted according to their correlation with the type factor. Such indices are, however, complicated, cumbersome and involve tedious calculations, thus limiting their practical usefulness.

Rees and Eysenck (1945) found that two measurements were highly correlated with the type factor, namely stature and transverse chest diameter. These measurements had similar saturations with the size factor and had similar saturations, but of opposite sign, with the type factor. The combination of these measurements in a ratio such as

$$\frac{\text{stature}}{\text{transverse chest diameter}}$$

would be free of the size factor and would tell us the individual's position on the body-type continuum. In order to have a convenient figure without decimals, and a mean near 100, stature was multiplied by 100 and transverse chest diameter by 6. The Rees-Eysenck body-build index for males is therefore

$$\frac{\text{stature} \times 100}{\text{transverse chest diameter} \times 6}$$

Tables for the ready calculation of the index are provided by Rees and Eysenck (1945) and a nomogram has been devised by Hamilton (1950) to permit ready calculation of the index.

As stature and transverse chest diameter differ with regard to variability, it might be suggested, on statistical grounds, that standard measure (i.e. the measurement expressed in terms of standard deviation

units from the mean) rather than absolute measurements should be used in the index. In order to determine whether this was, in fact, necessary in practice, the index was calculated both in standard and absolute measure on a group of 1,100 soldiers and the correlation was found to be + 0.94. In view of this high correlation, the more convenient use of absolute measurements was considered fully justifiable.

FIG. 9.3. FREQUENCY DISTRIBUTION CURVE OF
STATURE \times 100
TRANSVERSE CHEST DIAMETER \times 6
INDEX IN A GROUP OF 1,000 SOLDIERS SUFFERING FROM
NEUROSIS

In men, the index of body build, derived from factorial analysis was, therefore, extremely simple. In women, however, it was not possible to produce a simple index and a regression equation was calculated. From Fig. 9.2 it will be seen that there are four measurements which show a high correlation with the type factor, namely stature, symphysis height, hip circumference and chest circumference. These four measurements were utilized to form a regression equation as follows—

Index of female body build = + 0.59 stature + 0.47 symphysis height - 0.31 chest circumference - 0.164 hip circumference. The measurements in the regression equation are expressed in standard measure. The pros and cons for ratios and partial regression equations for assessing body build will be considered in greater detail later.

DISTRIBUTION OF THE REES-EYSENCK BODY-BUILD INDEX FOR MALES AND FEMALES

The Rees-Eysenck index of body build for men was calculated for normal groups, neurotic groups and psychotic groups, and it was always found that body build was distributed along a unimodal frequency distribution curve, approximating the normal frequency

Fig. 9.4. THE DISTRIBUTION OF REES'S AND EYSENCK'S BODY INDEX AMONG 2,423 NORMAL MINERS AND EX-MINERS IN THE RHONDDA FACH

curve with evidence of some degree of skewness in some of the groups studied. In one hundred normal soldiers, with a mean age of 30 ± 6 years, the Rees-Eysenck index had a mean of 100.1 ± 7.6 . Fig. 9.3 shows the distribution in 1,000 neurotic men, the mean

FIG. 9.5. FREQUENCY DISTRIBUTION CURVE OF A NEW INDEX OF BODY BUILD IN A GROUP OF FOUR HUNDRED WOMEN

being 104.4 ± 7.9 . The Rees-Eysenck index has also been calculated on 2,423 normal miners and ex-miners in the Rhondda Fach area of South Wales by members of the Medical Research Council Pneumoconiosis Unit (Fig. 9.4). It was found that the distribution in this group was slightly skewed to the right, showing that very high values of the index were relatively more frequent than very low values. It was found that the deviations from normality, though significant, were not marked.

The index of female body build consisting of the

regression equation, which is a function of stature, symphysis height, chest circumference and hip circumference was calculated for four hundred female Service neurosis patients successively admitted to Mill Hill Emergency Hospital. The mean was found to be $+0.385$ and standard deviation ± 3.68 . The frequency distribution curve of the index in this group is shown in Fig. 9.5. It will be seen that the distribution of the index of female body build approximates the normal frequency curve with some tendency to positive skewness. We find, as in the male group, a continuous variation in physique from the broad type, with high index values at one extreme, and a narrow type as its antithesis with low index values at the other.

We find, therefore, in both male and female groups a continuous variation in body build from one extreme to another, there being no evidence of bimodality or multimodality indicative of the existence of physical types in the sense of discrete and mutually exclusive categories. The male body-build index and the female body-build index, therefore, measure the position of the individual in the normal distribution curve of body build.

The extremes of the curve only, impress as well marked types. There are no natural dividing points and any demarcation of the curve into physical types, although convenient and at times necessary for purposes of research, will be arbitrary. Rees and Eysenck (1945) and Rees (1950), considered that statistically acceptable arbitrary demarcation points would be one standard deviation above and below the mean, dividing the curve into three classes—

1. Leptomorphs, with small breadth, width and circumferential measurements, relative to length;
2. Eurymorphs, with large circumferential measurements relative to length;
3. Mesomorphs with an intermediate relationship between lateral and linear measurements.

This division of the normal frequency distribution of body build is not intended in any way to convey the impression that these classes are disparate types. These categories of physique are ranges of body build objectively measured by new indices of body build and demarcated by statistical criteria for purposes of description and research.

An Evaluation of Anthropometric Indices in the Assessment of Body Build

Bodily measurements may be taken directly on the body or on standardized photographs or X-rays. From such measurements various indices of body build have been devised with the aim of providing objective methods of assessing physical type. A comprehensive list of such indices is given by Tucker and Lessa (1940).

It appears that, in the past, the construction of many of these indices has been based on an arbitrary selection of measurements which were combined in various ways in the hope that they would differentiate physical types.

Such arbitrary methods have hitherto been unavoidable, since inductively derived criteria for discovering which measurements were likely to be most discriminating in delineating and assessing physical types have, in the past, been lacking. Some indices were based on theories regarding the nature and origin of physical types; for example, the index of Viola, and its modification by Wertheimer and Hesketh (1926) is based on the theory of Viola (1925) that the relative growth of limbs and trunk volume are interdependent, in other words, the longer the limb the smaller the trunk volume, giving a microsplanchnic type; the shorter the limbs, the larger the trunk giving a macrosplanchnic (or megalosplanchnic) type.

A number of indices have been based on Kretschmer's (1921) description of types, using measurements thought to be useful in differentiating his types. Some studies have segregated contrasting types, such as the leptosomatic and pyknic types of Kretschmer, by visual impression. The two groups were then investigated anthropometrically and measurements showing the greatest differences between the groups used to form indices. This method has inherent disadvantages in that it merely provides an objective method of discriminating individuals, subjectively segregated into different physical types and cannot prove either the existence of the nature of physical types in the general population.

This method has been used to the best advantage by Strömngren (1937), who, by the method of least squares, was able to ascertain which measurements in combination most efficiently discriminated the leptosomatic types of physique from the pyknic types of physique. Strömngren's index is a function of stature, transverse chest diameter and sagittal chest diameter

according to the following equation: Strömngren's index = -0.04 stature + 0.12 transverse chest diameter + 0.156 sagittal chest diameter. Strömngren called the range $+0.15$ to -0.15 the frontier zone and index value outside these were said to denote pyknic and leptosomatic types respectively. He said that the average values for pyknics is $+1$ and the average value for leptosomes is -1 . These index values imply that the *habitus* of the majority of individuals can be classified into leptosomatic or pyknic types with a narrow frontier range separating the two antithetical types. If we plot the frequency

FIG. 9.6. FREQUENCY DISTRIBUTION CURVE OF STRÖMNGREN'S INDEX

distribution curve of Strömngren's index for random samples of the normal population, neurotic groups and psychotic groups, as shown by Rees (1943), we find a continuous gradation from one extreme to the other. If physique were naturally divisible into leptosomatic and pyknic types, we would expect the frequency distribution curve to be bimodal, but in fact we find it is invariably unimodal and approximating normal frequency distribution curve (see Fig. 9.6).

Rees (1943) compared pyknic, intermediate and leptosomatic physical types assessed by impression with the types delineated by the index values given by Strömngren. The distribution of types assessed by visual impression, in a group of one hundred normal soldiers was pyknic 24 per cent, intermediate 53 per cent, leptosomatic 23 per cent. It is interesting to note that this corresponds closely to the distribution of macrosplanchnic, normosplanchnic and microsplanchnic types found in Northern Italy by Viola (1932). Out of the twenty-four pyknics determined somatoscopically, only nine would be pyknic according to Strömngren's criteria, nine were in the frontier zone and six had leptosomatic values. Forty-five out of the fifty-three individuals somatoscopically assessed as being of intermediate physique were leptosomatic according to Strömngren's criteria, only five were in the frontier zone and three would be called pyknics. There was, however, complete agreement regarding the leptosomatic type. Taking the group as a whole 74 per

cent would be assessed as leptosomatic according to Strömngren's criteria, only 14 per cent intermediate and only 12 per cent pyknic. These findings do not necessarily mean that the index is thereby invalidated, but suggest that Strömngren's range of values for different physical types needs revision. Rees (1943) found that if one took the values of the 24th and 77th percentile as the upper and lower limits for the pyknic range and leptosomatic range respectively giving values of -0.13 and higher as indicating a pyknic physique, values between -0.133 and -0.79 indicating intermediate range of physique and values -0.79 and lower as leptosomatic physique, this gave a close agreement between the index value and somatoscopic diagnosis of type.

Strömngren's index has been criticized in recent years by Hjortsjo (1951, 1952), who stated that Strömngren's index did not take into account any variation in the relationship between sagittal and transverse chest diameters. He was able to demonstrate that persons of the same stature having either broad flat chests or narrow deep chests, can give identical values for Strömngren's indices.

CORRELATION BETWEEN VARIOUS INDICES

Ciocco (1936) pointed out that not only were we ignorant of the principles, which should underly the construction of various indices of body build or of the principles that had been utilized in the construction of indices in the past, but that we did not even know the degree to which they correlated with each other.

Rees (1949) pointed out that the correlation between various body-build indices was not only of intrinsic interest, but, under certain conditions, could provide a method of evaluating these indices. For example, if it were possible to take a number of body-build indices made up from different physical measurements on a random sample of the population and each index correlated with the others, this would provide a matrix of correlations which could be factor-analysed. If a general factor were found it would presumably relate to body type as this is what the indices are supposed to measure. It would then be possible to determine the saturations of the various indices with this general factor, and those indices having the highest saturation with it, should be the most valid ones for discriminating physical types.

This was done by Rees (1949) using thirteen body-build indices in a group of a hundred normal soldiers. Most of the indices were selected from the list given by Tucker and Lessa (1940) and were chosen because they contained the measurements available in the group (see appendix to this chapter). The list, therefore, does not necessarily comprise a representative sample and it will be seen that many of the indices are made up of similar measurements which would tend

to result in high intercorrelations. The fact that stature and chest measurements are common to so many indices undoubtedly influences the size of the correlations found and will result in these body indices being highly correlated with the general factor. This method, in this instance, could not be used as a means of validation but only as a means of determining the degree of correlation between various indices.

It was found that the Rees-Eysenck body-build index correlated highly with other indices and had a correlation of 0.76 with the general factor. The following indices also correlated highly with other indices: Brugsch's index, Pignet's index, Wertheimer and Hesketh's index, B. Marburg's index and the ratio $\frac{\text{stature}}{\text{sagittal chest diameter}}$. Other indices had a very low correlation and clearly did not measure the same thing.

COMPARISON OF INDICES WITH SOMATOSCOPIC GRADING

Rees (1949) anthroposcopically classified one hundred soldiers into seven grades according to descriptions given by Kretschmer and others. The seven-point scale ranged from the extreme pyknic to extreme leptosomatic type. Various body-build indices were subsequently calculated independently and correlated with the anthroposcopic grading. The Rees-Eysenck index was found to have the highest correlation and had an index of forecasting efficiency of 73 (Rees and Eysenck, 1945).

It was concluded that the Rees-Eysenck index reproduces the subjective rating of the anthropometric worker more faithfully than other indices and therefore provides an objective method which effectively replaces anthroposcopic grading.

THE RELATIVE MERITS OF BODY-BUILD INDICES CONSTRUCTED IN THE FORM OF RATIOS AND REGRESSION EQUATIONS

As we have seen, the data obtained from factorial analysis of anthropometric measurements provide us with relevant information for the selection of measurements likely to be effective in discriminating physical types. The saturations of various anthropometric measurements with the leptomorphic-euryomorphic factor indicate which measurements are likely to be most effective in assessing physical types. The ideal method, undoubtedly, is one which uses all those measurements having a reasonably high saturation with the type factor in the form of a regression equation. To establish a regression equation utilizing a large number of measurements would, as already noted, be of limited practical usefulness in view of the fact that it would be extremely cumbersome and would involve tedious calculations.

Rees (1950) in his factorial analysis of physical constitution in women found that it was not feasible

to devise a simple ratio as a body-build index as in the male group studied by Rees and Eysenck (1945), and utilized a regression equation consisting of four measurements having a high saturation with the type factor, namely stature, symphysis height, hip circumference and chest circumference. Burt and Banks (1947) found that a good multiple correlation with physical type could be obtained from stature, leg length, abdominal and shoulder girth and weight, which had a correlation of +0.95 with physical type as determined by 9 or more measurements.

Hammond (1953) calculated a series of regression equations for the type factors found in children. He points out that even with four or five measurements regression equations are rather cumbersome, since they require different weights for each age and sex group and possibly also social group to allow for the different means of standard deviations. He suggests, as an alternative simplification, the use of the ratio of measurements indicating opposite type tendencies. Hammond (1953) found that the ratio

$$\frac{\text{height}}{2 \times \text{chest circumference}}$$

had a correlation of 0.66 with the type factor in six-year-old boys and 0.73 in ten-year-old girls, and that it showed considerable constancy during the growth period. Another ratio, which he found useful was $\frac{\text{height}}{\text{hip girth}}$ which had a correlation with type of 0.83 for girls and also a high degree of constancy when calculated three years later.

The available evidence indicates that suitably constructed indices based on the results of factor analysis satisfactorily serve the purpose of providing a simple type assessment and have the great practical advantage of being more easily computed than indices consisting of regression equations.

Sheldon's Method of Classifying Varieties of Physique

Sheldon (1940) took standardized photographs of 4,000 college students. He sorted out these photographs and concluded that there were three main components in physique which he termed endomorphy, mesomorphy and ectomorphy. These terms were applied because it was considered that the three components of body build were derived from the three primary germinal layers, namely the endoderm, mesoderm and the ectoderm. Each individual was rated, by inspection, regarding each component on a 7-point scale, and the individual classified according to his rating in the three components.

Thus a 711 rating would be an extreme endomorph; this type would preponderate in breadth and circumferential dimensions. He has a round head, large, fat abdomen, weak arms with a great deal of fat in the

upper arm and thigh but with slender wrists and ankles. He has, relative to his general size, a large liver, spleen, alimentary canal and lungs, and a great deal of subcutaneous fat.

A 171 rating would indicate the extreme in mesomorphy. This somatotype shows bone and muscle development, predominantly, he has a cuboid massive head, broad shoulders and chest, muscular arms and legs, with the distal segments strong in relation to the proximal, having a minimum amount of subcutaneous fat.

A person rated as 117 would be an extreme ectomorph. This somatotype is characterized by linearity having a preponderance of length measurements and a relatively poor development in breadth, width and circumferential measurements. He has a thin face with receding chin, thin narrow chest and abdomen, spindly arms and legs; the development of muscle and fat is small in relation to his size, with a relatively large skin area and nervous system. Sheldon (1940) described eighty-eight somatotypes of which about fifty are common.

Sheldon's method may be regarded as an advance on previous typologies which tended to emphasize physical types as disparate and mutually exclusive categories. The method, essentially, describes human physique as a continuous variation in three components of body build with the somatotype representing an arbitrary demarcation of the person's position in the continuous scale.

Sheldon's (1940) method of classifying physique aroused great interest and has been used in all parts of the world. The method has incurred criticism on the following grounds—

1. *Subjectivity of method.* It is essentially a subjective method based on anthroposcopy of standardized photographs.

Sheldon (1940) tried to provide a more objective assessment of somatotype for the age range 16–21 by a series of seventeen diameters taken from the photograph in relation to the height $\left(\frac{3 \times \text{weight ratio}}{\text{ponderal index}} \right)$.

This, however, has not been found satisfactory and nowadays somatotype ratings are made from inspection of standardized photographs aided by reference to ponderal index values, which are now available for ages 16–35 years.

As the rating of components is a subjective procedure there is no certainty of agreement between different observers. It has, however, been demonstrated that the retest reliability of ratings is high with experienced workers. Brouwer (1956) found that ratings did not differ by more than half a unit by the same observer within an interval of some months. He also showed that two experienced observers did not

differ on more than half a point in 81 per cent of cases. Tanner (1954) also provided evidence that the correlation between highly trained experienced somatotypers is high but that some differences do occur between observers, and should be taken into account when comparing results from different laboratories.

2. *Somatotype not necessarily constant.* Sheldon's somatotype, by definition, should not change with age, nutritional state, physical activity or training. However, Lasker (1947) found that the somatotype ratings of photographs taken before and after partial starvation are usually unlike. Furthermore Newman (1952) found significant somatotype changes with increase in age in adult men.

3. Sheldon's hypothesis that the three components of physique are derived from the three primary germinal layers has not been established scientifically and, in fact, is not generally accepted.

The validity of the number of primary components is also contested. Humphreys (1957), for example, found that the correlations between endomorphy, mesomorphy and ectomorphy on 4,000 individuals calculated from Sheldon's data provided evidence for the existence of only two independent (but not necessarily valid) types of physique.

Similarly, Howells (1952) found from a factorial analysis of persons (instead of traits) in a group of individuals who were markedly dominant in one of the three components, endomorphy, mesomorphy or ectomorphy, that the three factors or scale arrangements of the persons extracted did not correspond to Sheldon's three components. His results suggest that ectomorphy, and endomorphy are not independent factors, but are opposite manifestations of one underlying factor and basically one continuum. These results are confirmed by a similar investigation carried out by Ekman (1951) which also strongly indicates that two rather than three components are appropriate to account for Sheldon's data, and Sills (1950), who correlated somatotype ratings with a number of measurement ratios, also found that ectomorphy was the opposite of endomorphy, rather than a separate factor.

MODIFICATIONS OF SHELDON'S METHOD

Parnell (1954) pointed out that Sheldon's system had inherent practical disadvantages. Standards of somatotype dominance are subjectively determined; many people object to being photographed in the nude and there are technical difficulties, also, in finding the necessary accommodation for the photographic and other equipment required. He accordingly modified Sheldon's method and proposed in its place a deviation chart profile of physique. The chart gives a standardized scale for height, weight and the ponderal index, for (1) bicondylar measurements of the humerus

and femur, (2) for maximal girth of the arm and calf, and (3) for the total of three skinfold measurements of subcutaneous fat. Parnell (1954) claims that the appropriate measurements for a given person recorded on the deviation chart give, at a glance, the main physical characteristics of the person and, with the aid of Sheldon's somatotype-ponderal index tables, a fairly accurate estimate of somatotype. Parnell (1957) further modified his technique and proposed ratings of the following: fat (F), muscularity (M), linearity (L) in place of Sheldon's endomorphy, mesomorphy and ectomorphy. He does not assert that the method is as suitable for somatotyping as photostcopy, but claims, in its favour, consistency and objectivity.

Parnell's (1954) modifications are criticized by Tanner (1954) on methodological and statistical grounds.

Hunt (1952) reports that Professor Hooton and his colleagues have attempted to devise a relatively fixed rating system, applicable to all adult ages and having an advantage of greater objectivity and simplicity than Sheldon's somatotyping technique. The system has three component 7-point scales. The first component is called fat and the second muscularity, both being rated from the inspection of nude photographs in much the same way as endomorphy and mesomorphy are by Sheldon's method. The third component is called attenuation and is derived from a 7-point scale based on the ponderal index $\left(\frac{\text{stature}}{3\sqrt{\text{weight}}} \right)$.

Hunt (1952) reviewing Hooton's approach, concluded that it expressed an unwillingness to dogmatize on the respective roles of heredity and environment, and is rather more operational than Sheldon's.

The existence of a high negative correlation between the first and third components (corresponding to endomorphy and ectomorphy respectively) in Hooton's system again raises the question whether they are opposite aspects of one continuum rather than a separate factor.

It will be noted that there is a marked similarity between Parnell's and Hooton's systems and both appear to acknowledge that one of the fundamental variations in body build appears to be linearity-laterality, corresponding to the leptomorphic-eury-morphic continuum, described by Rees and Eysenck (1945), with muscle and fat as additional factors determining variations in human physique.

Lindegard's Method of Assessing Body Build

Lindegard (1953) studied the variations in human body build, by means of anthropometric measurements, X-ray cephalometry and dynamometry, and concluded that there were four factors mainly responsible. These factors were designated length, sturdiness,

muscle, and fat factors. The method operates with continuous variables and involves rating the position of a person in scales for each factor. The factors are assessed as follows—

1. Length factor, from length of radius and length of tibia;
2. Sturdiness factor, from the breadth of the femoral condyle, bimaleolar and bistyloid breadths, distance between the nasion and centre of *sella turcica*, as determined by X-ray cephalometry;
3. Muscle factor, from dynamometric recordings of handgrip and foot press;
4. Fat factor, from body weight and extremal girths.

Lindegard (1953) showed that the length and sturdiness factors were correlated with the morphology of the skeleton in different parts of the body. For example, an individual with a large length factor and an average sturdiness factor, is characterized by long extremities, a broad deep and long trunk, a flattened cranial base form, a high upper face and a long mandible.

An individual with a large sturdiness factor, but average length factor, would have long hands and long feet, a broad chest, large biacromial diameter and bi-iliac breadth, large cranium and large face length.

An individual with a large muscle factor tends to have large extremal girths and high urinary creatinine excretion. A large fat factor is associated with softness and roundness of the body. Lindegard (1953) claimed that these variables express not only the outer configuration of the body, but also its inner structure.

The length, sturdiness and muscle factors are determined directly on the individual. The fat factor is deduced by comparing the weight and extremal girths with the skeletal build and the muscle factor.

Lindegard (1953) plots the four factors on a graph in terms of standard deviation units and he claims that this gives a clear impression of the entire body build of an individual.

He finds that length, sturdiness and muscle factors are interdependent, and he attempts to deal with this by regression techniques giving a relative sturdiness factor and a relative muscle factor. The relative sturdiness factor expresses the skeletal sturdiness in relation to the length factor. The relative muscle factor is expressed by the dynamometric recording in relation to skeletal build as represented by stature.

Lindegard's (1953) method has been criticized because of the possibility that dynamometric recordings may be considerably altered within a short space of time by training and exercise, and may also be influenced by age, disease, etc. The method, however, has the great advantage of being objective.

Comparison of Factorial Types with Sheldon's Somatotypes

The results obtained from factorial analysis of groups which are different not only in age, sex and racial status, but also in selection of anthropometric measurements and technique of analysis used, exhibit a high degree of agreement in the factors elicited, but provide no factors comparable to Sheldon's somatotypes. Even when factorial analysis has been specifically carried out to validate Sheldon's somatotypes, e.g. the analysis of persons by Howells (1952) and Lorr and Field (1954), the results do not support Sheldon's threefold primary components of physique.

The available evidence suggests that endomorphy-ectomorphy is one continuum rather than two separate components.

Tanner (1952) demonstrated that ectomorphy is practically the same as Burt's leptosome factor, and Hammond (1957) considers that the pachysome pole of the type factor approximates to the endomorph. Parnell (1957) compared the Rees-Eysenck index with somatotype in a group of students. He found the highest index values were found in Sheldon's extreme ectomorphs and that Sheldon's ectomorphs and Rees and Eysenck's leptomorphs had much in common. He found that the lowest values of the Rees-Eysenck index were found in ectopenic mesomorphs, i.e. subjects who are low in ectomorphy, but who exhibit mesomorphy rather than endomorphy. Comparison is not really feasible as Parnell's types include assessments of muscle and fat, whereas the Rees-Eysenck index is based on skeletal measurements. Thus the results of factorial analysis do not provide support for Sheldon's threefold component somatotype system.

COMPARISON OF SHELDON'S AND LINDEGARD'S SYSTEMS

Lindegard (1956) compared his classification of physique with that of Hooton's modification of Sheldon's method and the results are given in Table IX.3.

It is noteworthy that here again we find evidence suggesting that ectomorphy-endomorphy is probably a continuum as it has high negative and high positive correlations respectively with the fat factor of Lindegard (1953). The validity of mesomorphy is sometimes questioned and Lindegard found that mesomorphy correlated with muscle but not with the sturdiness factor. This suggests that Sheldon's method is based on the outer configuration of the body rather than on its composition as implied by Sheldon (1940).

Tissue Component Analysis

The assessment of the relative development of tissues such as bone, connective tissue, fat and muscle is a newly developing and promising field of somatology. It is by no means a substitute for other systems or

TABLE IX.3
COMPARISON BETWEEN SHELDON'S (HOOTON'S) COMPONENTS AND LINDEGARD'S FACTORS

Sheldon's system (Hooton's modifications)	Lindegard's (1953) factors			
	Length	Sturdiness	Fat	Muscle
Endomorphy (Hooton's 1st component)	Low positive insignificant correlation (+ 0.05)	Not related	+ + + + ($r = 0.96$)	+ (+ 0.20)
Mesomorphy (Hooton's 2nd component)	Small negative correlation (— 0.19)	Not related	+ + (+ 0.32)	+ + ($r + 0.29$)
Ectomorphy (Hooton's factor of attenuation)	+ + + ($r = 0.21$)	Not related	— — — High negative correlation (— 0.8)	— Small negative correlation (— 0.14)

methods of studying body build and could be complementary to factorial studies of physique, Sheldon's (1940) and Lindegard's (1953) systems.

The relative thickness of bone, fat and muscle can be measured by standardized X-rays of the calf (Stuart and Sobel, 1946; Reynolds, 1949; Reynolds and Askawa, 1950). It has been shown that the relative amounts of fat, muscle and bone in the calf are more or less independent of each other. Ectomorphs have the smallest amount of bone, muscle and fat, mesomorphs the largest amount of muscle and bone, and endomorphs the largest amount of fat (Reynolds, 1949; Reynolds and Askawa, 1950).

ASSESSMENT OF FAT

The development of adipose tissue can be assessed by a number of methods, in addition to the above X-ray method.

1. *Measurement of thickness of skinfolds* is described by Cureton (1947), Edwards (1950*a* and *b*), Brozek and Keys (1951), Brozek (1953), Tanner and Whitehouse (1955), Parnell (1954*a*, 1957).

Special calipers are used for this purpose and optimal requirements for such instruments are described by Edwards *et al.* (1955). A caliper designed to meet these requirements has been produced by Tanner and Whitehouse (1955).

Edwards (1950) took repeated skinfold measurements in some fifty different sites and was able to demonstrate that variation in body weight is accompanied by variation in the subcutaneous thickness of skinfolds.

2. *Physico-chemical methods.* McCance and Widdowson (1951) utilized physico-chemical methods for estimating body fat. The total body water was assessed by measuring the dilution of an introduced chemical substance, which is freely diffusible in all the

body fluids (e.g. antipyrine) and from this the lean body mass is calculated. This subtracted from the total body weight leaves the weight of fat and bones. The weight of bones can be estimated from the weight of a comparable dry skeleton. This method is complicated and is of doubtful reliability.

3. *Specific gravity method.* Another method involves the calculation of the total amount of fat and water in the body. The amount of fat is directly related to the specific gravity which can be calculated by measuring the body volume by stereoscopic photographs, or by underwater weighing. The total body water content can be estimated by chemical means and it has been found that total body water and total body fat content are inversely proportional to each other.

4. Lindegard (1953) assesses the fat factor by eliminating the influence of bone and muscle tissues on body weight and from the girths of the extremities by partial regression calculations. He finds that the fat factor measured in this way correlated to the extent of + 0.55 with subcutaneous fat as measured by the technique of Reynolds (1950).

Brozek and Keys (1951) using the specific gravity method, found that age and sex factors influenced fat content in the body. Between ages 19–25 years 10 per cent of body weight was fat and between 45 and 55 years fat accounts for 21 per cent of body weight. The mean fat content was found to be about 10 per cent higher in normal females than in normal males of the same age.

THE MUSCLE FACTOR

An assessment of the development of muscular tissue in relationship to other morphological characteristics is included in the typological systems of Sheldon (1940), Parnell (1954, 1957) and Lindegard (1953). If muscular development is to be used for

assessing body build and physical type, it is important to know its degree of constancy during a person's life. Muscularity is a factor which, theoretically, is capable of being modified by a number of conditions. Apart from disease, a number of conditions during normal active life may influence muscularity, e.g. the habitual level of physical activity which a person engages in during his occupational or recreational pursuits. Muscularity may also be altered by intensive physical activity over a comparatively short period of time. An attempt was made to assess the effect of habitual physical activity on the muscle factor by Lindegard (1956) in a group of two hundred and eight Swedish men who had left different occupations to enter military service. They were examined soon after entry to military service and subsequently after a period of six months during which time the men had been subjected to ordinary military training. The muscle factor was assessed by dynamometric recordings of the gross muscular strength of certain groups of muscles, viz. handgrip, shoulder thrust and shoulder pull. It was found that the dynamometric values initially recorded on entry for military service were highest in individuals belonging to the heavy or manual worker group, and were lowest in clerical workers. It was found that dynamometric measurements increased on the average by about 3 kg during the observation period of six months. Shoulder thrust and shoulder pull exhibited more variability than handgrip. These findings indicate that dynamometric measurements as an index of the muscular factor show considerable variability during a short space of time, and accordingly are less valid and reliable as measures of constitution. The effect of intense physical activity on a group of healthy men was studied by Tanner (1952). The group consisted of ten healthy men predominantly of mesomorphic physique who underwent a course of physical training by weight lifting over a period. The effect of the weight training on the physique was studied by means of anthropometric measurements and by standardized photographs from which further measurements were taken. These were taken twice before the onset of training, at intervals of three weeks during training and at four months after training had ceased. The largest increase was found in upper arm circumference in which every subject showed a significant increase. All measurements tended to revert to their pre-training values at four months after cessation of training. Tanner (1952) found that there were no significant changes in somatotype rating, but that the effect on regional somatotypes and dysplasia (as defined by Sheldon) was more marked. There were significant increases in strength in various tests ranging from 10 per cent to 80 per cent.

Lindegard (1956) found that the muscle factor was positively correlated with the sturdiness factor to the

extent + 0.26. This indicates that when the muscle factor is compared with other variables, it should be analysed independently of the sturdiness factor by means of partial correlation calculations. A positive correlation of 0.22 was found between muscle and length factors.

In conclusion, we may state that the muscle component of body build is difficult to measure satisfactorily. In addition to this disadvantage, it has been demonstrated that significant changes can occur with intensive exercise and as a result of habitual level of physical activity.

The available evidence indicates that muscle and fat are capable of showing marked variations in the individual during a comparatively short period of time and are far less constant than skeletal measurements for the study of the physical aspects of human constitution.

The Role of Genetic Factors in Determining Body Build

Body size, body shape, as well as many other morphological attributes such as the relative development of different organs and tissues, are a function of growth rates which in turn are largely determined by genes. Environmental factors, particularly nutrition and disease can modify, to some extent, these genetically determined characteristics, particularly if they occur during the growth period.

An assessment of the relative importance of genetic and environmental factors in determining various bodily dimensions can be made from the results of twin studies. Dalberg (1926) compared the variability of anthropometric measurements in identical and non-identical twins. The results showed that heredity accounted for 90 per cent of the variability of body length measurements and slightly less for the variability of body breadth, head and face dimensions. This finding is also supported by the results of Newman, Freeman and Holtzinger (1937), derived from a study of nineteen identical twins brought up apart from infancy. Newman *et al.* (1937), also found that there were no significant differences in height, weight, head length and head breadth in identical twins from a group of fifty pairs brought up together in the same environment.

The majority of bodily dimensions and the variations in body size and body shape have normal frequency distributions. This is in keeping with the hypothesis of multifactorial inheritance of these attributes. Davenport (1923) who classified individuals according to degree of linearity of body build for comparing physical type in parents and offsprings, produced results which also supported the view that multiple genetic factors are responsible for the inheritance of physical type. Palmer (1934) put forward

evidence that the genes controlling the rate of physical growth are, to a large extent, independent in action from those controlling the final size achieved. It has also been shown that in animals general body size is largely determined by genetic factors. That this is true of mammals was shown by Castle (1922, 1941) and of birds by Walters (1931). It is interesting to note in this connexion that Gregory and Castle (1931) demonstrated that large and small races of rabbits exist which, as early as thirty hours after fertilization, show a difference in the number of blastomeres.

There is a great deal to be learnt about the genetics of the factors underlying body size, body shape and the relative development of different parts and tissues of the body, and this is a field which urgently merits the serious attention of genetic research workers.

The Relationship between Physical Type and Growth Processes

D'Arcy Thompson (1942) pointed out that the form of an organism is a function of growth, whose rate varies in different directions and must be regarded as an event in space-time and not merely a configuration in space.

Studies of growth in the human being and in animals have considerably elucidated the nature of the factors underlying the variations in human physique and promise to be a fruitful field for future research. Studies of growth in the human are of two main kinds—

1. Longitudinal studies which deal with the changes in an individual over a period of time. A number of longitudinal studies on growth and development during childhood, adolescence and later, are now in progress in various parts of the world, and the results should provide invaluable information for the science of somatology. A review of these projects is given by Garn (1957).

2. Cross-sectional studies which deal with individual differences at different ages. Most of the published work on growth utilizes this method.

In so far as the form of the human being is determined by the rate of growth in various directions, it is of fundamental importance to know how and when the types of physique found in the adult are determined. There is evidence that there are not only changes in growth resulting in increase in size of the body but also changes in differential growth, giving rise to changes in bodily configuration. D'Arcy Thompson (1942) from study of growth curves of weight and stature found differences corresponding to changes in the shape of the child as he grows. He states that the infant stores fat and the active child runs it off again. Between 4 and 5 years the increase of weight is at a minimum, but a fresh start is then made and the small schoolboy grows stout and strong. There is evidence

according to Tanner (1947a) of an increase in the rate of growth between $5\frac{1}{2}$ to $7\frac{1}{2}$ years, which has been referred to as the midgrowth spurt, and that the changes which appear to be mainly concerned with the midgrowth spurt are lateral dimensions. A person who exhibits a large midgrowth spurt and a small adolescent spurt will end up different in bodily form from a previously similar individual who had had a large adolescent but a small midgrowth spurt. The nature and significance of the midgrowth spurt is still *sub judice*, and it will probably be necessary to await the results of longitudinal studies of individuals from birth to adult life before its significance can be determined. The available evidence, however, indicates that all leptomorphic-eurymorphic differences found in adults cannot be attributed to differences between midgrowth and adolescent spurts.

Tanner *et al.* (1956) carried out an interesting study on a group of individuals who had been measured anthropometrically between 1925 and 1932 by the late Professor Alexander Low. Low (1952) measured a series of sixty-five boys and fifty-nine girls at birth and at subsequent birthdays up to and including age 5. Tanner and co-workers (1956) re-measured and somatotyped as adults aged 25 to 30 years, about two-thirds of the group. They found that the correlation of birth measurements with later measurements was much lower than the intercorrelation of later measurements between themselves. It was evident that the size of the new-born babe was only very slightly related to the size of the adult or even to the size of the two-year-old. They found evidence that the inherent growth characteristics of the child asserted themselves after birth, and the correlation between the childhood measurements and adult measurements rose sharply. They concluded that it was possible to predict adult size as reliably at the age of 3 years as it was at the age of 4 or 5 years.

Carter and Krause (1936) analysing the data of Bakwin and Bakwin (1929) on neonates, found evidence of a general factor and of a well-marked bipolar leptomorphic-eurymorphic factor, which accounted for 10 per cent or more of the variance. Bailey and Davis (1935) in a study of growth during the first three years of life also found evidence of a general growth factor which retarded rapidly at first then more slowly throughout the thirty-six months. They found that disproportionate growth rates occurred at certain periods, and corresponded to changes in body build. They found that lateral growth, giving rise to chubbiness, increased rapidly during the first eleven months, with a more gradual increase of longitudinal growth up to this age.

Mullen (1940) carried out a factorial analysis of anthropometric measurements in groups of girls, ranging in age from 7 to 17 years, and found in all

age groups a general factor and two group factors corresponding to the bipolar leptomorphic-eury-morphic factor of Rees and Eysenck (1945). Similarly Macloy (1940) in a study of groups of boys and girls at various ages from birth to puberty, found evidence of a general factor as well as a type factor. Hammond (1957) carried out a factorial analysis of anthropometric data for individuals covering the period from birth to the age of 5. He included a group of infants from Leeds, data from Aberdeen, the infants collected by Professor Low referred to above, and also Carter and Krause's (1936) analysis of infants' measurements. He found that the evidence indicated length, girth and breadth types similar to those found in later life, and was uniform throughout the age range. He found that the type consistency was low in infancy and increased throughout the school ages. Hammond (1953) reported results of studies of groups of English children ranging in age from 5 to 18 years and consisting of groups differing in socio-economic status, comprising 1,430 private school children and 1,537 free school children. Measurements were repeated after three years in the children still attending the schools. He found in all groups a body size and a type factor indicating a pachysome-leptosome dichotomy corresponding to the leptomorphic-eury-morphic dichotomy of Rees and Eysenck (1945). He also found that the constancy of individual type values over periods of two or three years, as shown by the correlation between the first and second measurements, ranged from 0.65 to 0.92 for the different age, sex and racial groups, but the correlation tended to be lower about the time of puberty. He found that 11 per cent of the boys up to the age of 13 had changed their type, and up to the age of 14 this figure was 18 per cent. Among the girls, 8 per cent of those who had reached the age of 9 and 22 per cent of those who had reached age 10 to 13 years were found to have changed their physical type and after 14 years the figure fell to 12 per cent. He found the ratios $\frac{\text{height}}{\text{chest circumference}}$ and $\frac{\text{height}}{\text{hip girth}}$ were useful in the assessment of physical type and changed very little with age.

The available evidence suggests that the two main factors isolated by Rees and Eysenck (1945), and by Burt (1937 and his followers, occur in all age groups in both sexes.

The evidence also strongly indicates that physical type in a large proportion of individuals tends to remain relatively constant, as shown by the work of Hammond (1953, 1957).

Sex Differences in Body Build

A number of investigations have recently been devoted to the study of the differences in various morphological characteristics between males and

females. These studies have utilized different methods, including—

1. anthropometric measurements treated by statistical techniques, such as factorial analysis and discriminant functions;
2. comparison of the distribution of physical types;
3. comparison of the distribution of the relative amounts of various tissue components, such as fat, muscle, bone, etc.;
4. anthroposcopy, including general appearance, contours of the body and ratings of specific features.

ANTHROPOMETRIC DIFFERENCES AND DIFFERENTIAL GROWTH RATES BETWEEN SEXES

Rees (1950) carried out a factorial analysis of anthropometric measurements on two hundred adult females and compared this anthropometric data with that of two hundred neurotic soldiers and one hundred normal soldiers of similar age distribution. It was found that the male groups exceeded the female group in all measurements except hip circumference. Females, however, were found to have a longer trunk relative to stature. There was considerable overlapping in all measurements. The variations in body build were found to be determined, as already indicated, by a general factor of body size and a type factor. In the female group, the anthropometric measurements having the highest correlation with the type factor were symphysis height, stature, chest circumference and hip circumference, whereas in the male group stature and transverse chest diameter had the highest saturations with the type factor.

Tanner (1951) used the statistical method of discriminant functions to ascertain the best possible discrimination between males and females with regard to biacromial diameter and bi-iliac diameter. He found that the best index for discriminating the sexes was $3 \times \text{biacromial diameter} - \text{bi-iliac diameter} - 82$. He found that this only misclassified 6 per cent of males and 20 per cent of females.

Lindgard (1953) compared a group of adult men and women anthropometrically. He found that the males were significantly greater in the mean value of the majority of measurements than the female group. Differences between the sexes were smallest regarding two measures of pelvic breadth, namely the bi-iliac and interspinous breadth. Tanner (1955) reports that the chief differences in body shape between men and women are that men have, on the average, broader shoulders, narrower hips and longer upper and lower extremities than women, which is in contradistinction to the findings of Lindgard (1953).

The differences found in physique between adult men and women can be explained by sex differentials

in growth and growth rates. Thompson (1946) reviewing the relevant literature, concluded that boys exceed girls in mean weight until 11 years, and that from 11 to 14 years girls exceed boys and by 15 to 16 years superiority is regained by boys. By 20 years the mean weight of males exceeds that of females by 20 per cent. Girls, although smaller physically, tend to be more mature than boys in development, as shown by the earlier puberty and by the earlier pre-adolescent growth spurt. In males from puberty to maturity the growth in trunk and limbs is at first equal, then there follows a period of rapid trunk growth, circumferential growth continuing longer than growth in length. In females from puberty to maturity, the trunk elongates in the lumbar region and the pelvis enlarges, whilst the lower extremities cease to grow in proportion to the trunk. Tanner (1955) confirms that girls gain a temporary lead when their adolescent growth spurt starts and, for a time, are larger in all dimensions than boys. This lasts for the period 11 to 13 years, and then the boys' adolescent growth spurt starts and continues with greater intensity. Tanner (1947*a*) pointed out that the major relative growth velocity during the adolescent spurt is, of the hips in girls, and of the shoulders in boys.

Differences in physique have been observed between those who mature early and those who mature late. Baldwin (1921) found that boys and girls who were tall before puberty begin adolescence earlier than those who are short. Tanner (1955) demonstrated that somatotypes are related to the age of maturity. He found, for example, that ectomorphy increases steadily from a rating of 3.4 in the earliest maturers, to a rating of 4 in the latest maturers. Mesomorphy had the highest rating in the earliest maturers, whereas endomorphy showed no consistent trend at all. Barker and Stone (1936) and Worrell (1939) found that pyknic girls have the menarche eight months earlier than leptosomatic girls. Tanner (1955) states that early maturers, especially boys, are likely to be high in mesomorphy and low in ectomorphy. In girls early maturers may be somewhat high in endomorphy, but he states that these conclusions are tentative and that further data are required before definite conclusions can be reached.

SEX DIFFERENCES IN DISTRIBUTION OF PHYSICAL TYPES AND IN TISSUE COMPONENT ANALYSIS

The study of body types has, in the past, received far less attention in women than in men. Kretschmer (1921) pointed out that the types of physique described by him were less easily diagnosed in women, and Sheldon (1940) pays comparatively little attention to somatotypes in women. Sheldon, Dupertuis and McDermott (1954) discuss the sex factor in somatotypes and state that women are much more endo-

morphic than men and that all ages are heavier in proportion to stature. The mean $\sqrt[3]{\frac{\text{height}}{\text{weight}}}$ index for 4,000 college men was 13.19 and for 4,000 college women was 12.84, and the distribution of somatotypes in women was markedly different from that in men.

A comparison of the distribution in tissue components in males and females was carried out by Reynolds (1949) who utilized X-ray photographs of the calf and confirmed that females have on the average greater thickness of subcutaneous fat than men. Reynolds and Askawa (1950), claimed that the sex of a person X-rayed can be told with 90 per cent success from the relative amounts of fat and bone in the calf. Edwards (1950*b*) using skinfold calipers, found that skinfolds were one and a half times as thick in women as in men, and that this was due to subcutaneous fat.

Anthroposcopic Differences

Draper, Dupertuis and Caughey (1944) give descriptions of impressionistically determined morphological differences between males and females. They emphasize such features as the carrying angle of the upper extremity, the relative dimensions of pelvic and shoulder breadth, the characteristic outline of the space between the lower extremities when the heels are approximated, the silhouette of the outer part of the calf, the slope of the shoulders and the outward curve of the hip and thigh, all of which tend to show characteristic differences between males and females.

Androgyny (Gynandromorphy)

The terms androgyny and gynandromorphy refer to the degree of femininity of body build in the male and the degree of masculinity in body build of the female.

The study of androgyny and various other constitutional attributes has been the subject of a number of investigations recently. Androgyny has been assessed by two distinct methods—

1. Subjective procedures consisting of assessment of general appearance and ratings of special features. This method was used by Sheldon (1940), Seltzer (1945), Bailey and Bayer (1946), Draper, Dupertuis and Caughey (1944) and Parnell (1954).
2. Objective, anthropometric methods, as used by Tanner (1951).

Tanner (1955) considers that androgyny, in contrast to somatotype, is determined by events taking place at adolescence. Relationships between androgyny and various other attributes have recently been studied. Parnell (1954) studied the relationship between the relative incidence of masculine and feminine physical traits and academic and athletic performance. He

found that academic distinction was associated with a significant trend towards a greater degree of feminine traits and that athletes, as would be expected, showed a higher incidence of strong masculine traits.

Lindegard and co-workers (1956) correlated various traits of masculinity with Sjöbring's personality variables and with various endocrine functions, but found no significant relationships. Seltzer and Brouha (1943) found that a superior degree of physical fitness could only be achieved by persons with a strong masculine component in their body build, and that individuals having physiques weak in masculinity, tended to have poor effort tolerance. In a recent study by Coppen (1957), using Tanner's index in a study of toxæmia in pregnancy, it was found that patients who developed toxæmia had a higher incidence of masculine features in body build than those who did not develop toxæmia.

Dysplasia in Physique ✓

Dysplasia is the term applied to the disharmonious development of one or more parts of the body and is assessed by the extent to which one part of the body fails to harmonize with another. The term is used differently by various workers who use different methods and criteria when they are making assessment.

Kretschmer (1921) described a number of dysplastic types of physique which he considered were due to glandular disturbances. He assessed these types anthroposcopically and considered that they had a biological affinity to schizophrenia.

Viola (1932) attempted to make a statistical assessment of dysplasia by finding the total of the percentage deviation of various bodily measurements from the average.

Sheldon (1940) uses the term dysplasia to denote the degree with which somatotype ratings for different parts of the body fail to agree with each other. Sheldon (1940) assesses dysplasia anthroposcopically and there are no objective methods available. The assessment of Sheldon's dysplasia is a complex task and probably can only be done with accuracy when the dysplasia is gross.

Howells (1952) from his factorial study of Sheldon's somatotypes, found that the results only supported the existence of two main components (or factors) underlying physique, and that therefore the whole concept of dysplasia, as expressed by Sheldon (1940), needed revision.

The causes of dysplasia are not known. The questions, whether genetic factors are the main determinants of the disharmonious growth of different parts of the body or whether disturbances interfering with the growth of certain parts of the body during the developmental period are predominantly responsible,

cannot be answered at present and must await further research.

Constancy of Body Type in Adult Life

The question of the degree of constancy of body type during adult life is of fundamental importance in studies on human constitution. Little research work has been carried out on the changes in physical dimensions and proportions during adult life and published results differ widely. Brugsch (1918) found that narrow-chested types developed into normal-chested types in one-third of all cases, between the age of 25 and 35 years, and that some normal-chested individuals can change with increasing age, to the wide-chested type.

Mills (1917), however, found in a study of 1,000 persons that no individual changed from one major class to another with increasing age, and that the only changes were in subtypes. Similarly Viola (1932) maintained that the types of *habitus* described by him, viz. the longtype and the brachytype, were not altered by age.

Bauer (1926), using Sigaud's (1914) classification of types, found that the broad type (the digestive type) occurred more frequently among subjects of advancing age.

The ideal method of investigating the effect of age on body type would be to carry out anthropometric investigations in a random sample of the normal population at regular intervals throughout infancy, childhood, adolescence, maturity and senescence. Results from such studies are not yet available. Another method which is available, but which must be regarded as second best, is to make a cross-sectional study of a random sample of adults of different ages.

Rees and Eysenck (1945) carried out a factorial analysis of seventeen anthropometric measurements in a series of two hundred soldiers. The age ranged from 19–55 years, with a mean of 34 years and standard deviation of 5.89. The Pearson product moment correlation coefficients between age and seventeen absolute physical measurements are shown in a table from which it will be seen that most of the traits show a negative correlation with age, indicating a slight tendency for individuals of the old-age groups to be smaller in these measurements. Chest and hip circumference, trunk and sternal length, show low positive correlations indicating a slight tendency for the older individuals to be larger in these measurements. The only correlations which are statistically significant are trunk, sternal length and sagittal chest diameter. The statistical significance is of a low order, the odds against the correlation being due to chance, being about 20:1.

Four body-build indices (*see* appendix to this

chapter for formulae) were calculated for the group and correlated with age—

1. The Morphological index
2. The Pignet index
3. Strömrgren index
4. Brugsch's index.

The Morphological index showed the highest correlation, viz. -0.245 . Brugsch's index was next with a correlation coefficient of $+0.141$. The correlation for Pignet index was -0.098 , and the Strömrgren index $+0.097$. All the correlations suggest a slight tendency for older individuals to be more broad in build. The correlation coefficient of the Morphological index is statistically significant at the 1 per cent level and Brugsch's index at the 5 per cent level.

Age was found to have a saturation of -0.236 with the type factor, indicating a tendency for older members of the group to have relatively greater breadth, width and circumferential dimensions in contrast to length. The results obtained by Newman (1952) who studied the problem of stability in body build by examining a series of 40,000 individuals photographed by the U.S. Army and typed at Harvard University according to Hooton's modification of Sheldon's method are in conformity with these findings. The age range varied from 18–35 years. It was found that definite, although limited, changes associated with age occur in this group. The first and second components, corresponding with endomorphy and mesomorphy increased with age, while the third component corresponding to ectomorphy, decreased. The correlation between the first and second components, and the first and third components, increased with age, but the second and third components retained the same magnitude of association.

Lasker (1953) in a study of adult Mexican males, and Hooton and Dupertuis (1951) in a series of 10,000 Irish males, found that stature and sitting height reach a maximum in the thirties, and decline thereafter. Hooton and Dupertuis (1951) found a tendency for chest measurements to increase throughout adult life. These findings conform with our results.

Increase in head measurements has also been reported by these workers and also by Buchi (1950) in a study of one hundred and ninety-six Swiss adults who were re-examined after an interval of nine years.

Lasker (1953) discussing the possible reasons for variation of anthropometric measurements with age, suggests that the change may occur mainly in the soft tissues, particularly cartilaginous and adipose tissues. The effect of adipose tissue on anthropometric measurements was clearly demonstrated by the work of Keys *et al.* (1950), who found a significant decrease in various bodily measurements during starvation.

Lasker (1953) believes there is strong evidence that the increased size of the face may, to some extent, be caused by oppositional growth of bone, although there may possibly be some changes in overlying soft tissue. He considers that it is probable that incremental growth changes continue for much longer than most anthropologists previously thought possible.

Environmental modifications of physique may occur as late as the third decade and subsequently. Lasker (1951) demonstrated the extent to which this was possible. Mexicans, who had resided in the United States, even temporarily, differed in size and proportions from their less perambulatory neighbours. He found that the differences were a function both of length of residence and age at emigration.

The available evidence, therefore, indicates that limited, but significant changes can occur in bodily dimensions and proportions with increasing age during adult life, and this emphasizes the extreme importance of controlling the age factor in constitutional studies in adults as well as in children.

Physiological Functions in Relation to Body Build

The physiological attributes of human constitution and their possible relationships to morphological, psychological and immunological features, have received comparatively little attention from research workers. The field of physiology, including endocrine and metabolic studies, is clearly an important one, as it might serve to bridge the gap between morphology, temperament and susceptibility to disease.

Tanner (1944) studied the relationship between Sheldon's components of physique and body temperature, cardiovascular functions and respiratory rate. He found that oral temperature and respiratory rate at rest, were correlated positively with ectomorphy and negatively with endomorphy. When he used an estimated leptosomic factor score instead of ectomorphy, the correlations were higher, $+0.32$ with respiratory rate, and -0.39 with oral temperature. Both ectomorphy and mesomorphy were found independently to have a tendency for higher oral temperature.

Gertler, Garn and Sprague (1950) and Tanner (1951a) have shown that the level of blood cholesterol is positively correlated with endomorphy. Kretschmer (1948) reported that serum albumin and serum antitrypsin are higher in leptosomes than pyknics.

The relationship between body build and the excretion rate of adrenal corticoids has been studied by a number of workers recently. Gertler *et al.* (1954), in a study of fifty individuals suffering from coronary disease, found that those with predominantly mesomorphic body build tended to excrete the highest amounts of 17-ketosteroids. The ectomorph, on the average, excreted the lowest amount of 17-ketosteroids, and endomorphic individuals were intermediate in this

respect. Tanner (1955) found a correlation between increased excretion of androgens and the accelerated development of muscular strength in a longitudinal study of growth in adolescent boys. Genell, Jensen and Lindegard (1956) studied the urinary excretion of a number of different adrenal cortical hormones in one hundred and ninety-seven Swedish twenty-year-old healthy Army men and found that the muscle factor was positively correlated with secretion of 17-ketosteroids and 17-hydroxycorticoids.

Seltzer (1940) compared oxygen uptake and utilization in different types of physique and found that leptomorphic individuals had a lower level of mechanical deficiency as measured by oxygen-uptake experiments than those of broader body build. Seltzer and Brouha (1943) also found that the higher the androgyny the worse the exercise tolerance in normal men.

The study of relationships between physical type and physiological and biochemical functions is in its infancy and it remains to be seen whether the advent of improved techniques in physiology, biochemistry and body build assessment will reveal greater correlations.

Physique, Personality and Neurosis

The tendency to relate physical with psychological characteristics has its roots in antiquity and indeed formed a prominent part of the humoral theories of Græco-Roman physicians. During recent times studies designed to investigate such relationships can conveniently be classified according to the physical characteristics or the particular physical typology used as the basis for investigating correlations with personality, temperament, character, behaviour, neurotic illness, etc.

STUDIES BASED ON VIOLA'S TYPOLOGY

Viola (1925) described three main types of physique: the macrosplanchnic type, possessing a large trunk, in comparison with the development of the limbs, having large development of horizontal and circumferential dimensions and relatively small development of vertical dimensions. The microsplanchnic type, its antithesis, has a small trunk and long limbs with vertical dimensions preponderating over horizontal dimensions. Intermediate between these types is the normosplanchnic type having a harmonious development of trunk and limbs. Viola considered that the macrosplanchnic type had an overdevelopment of the vegetative system, whereas the microsplanchnic type had an overdevelopment of the animal or locomotive system (viz. the body musculature, nervous system and skeleton). The macrosplanchnic and microsplanchnic types were believed to differ in intellectual capacity and temperamental characteristics attributable to

differences in the relative development and activity of the vegetative and animal systems.

Pende (1928), a pupil of Viola, extended Viola's classification by introducing a number of endocrine variations. He considered that there were two main physiological biotypes—

1. The anabolic biotype, which he equated with megalosplanchnic body build, having specific temperamental and hormonal characteristics;
2. The catabolic biotype which was equated with microsplanchnic physique, having specific endocrine and neuro-vegetative characteristics.

However, these relationships are mainly speculative and lack scientific and experimental validation.

Naccarati (1934), using an index based on that of Viola, investigated the body build of one hundred male neurotic subjects. By means of the index he classified individuals into microsplanchnic, normosplanchnic and macrosplanchnic types. He found that the neurotic group had a higher proportion of extreme physical types than a normal group of similar sex and age distribution. He found that emotional neuroses (under which category he included both hysteria and anxiety states), were associated with a more macrosplanchnic type of physique than the normal group, whereas neurasthenic patients were more microsplanchnic than both the normal and the emotional neurosis groups. Naccarati's work is difficult to assess because of his terminology and classification of neurosis. There would appear to be no valid reason for including such contrasting conditions as hysteria and anxiety state in the same diagnostic class. Similarly the term neurasthenia is extremely unsatisfactory, having for many years been ill-used and over-used. His findings are also unacceptable because of lack of statistical treatment of the data.

Greenwood and Smith (1941), following the work of Boldrini (1925), who demonstrated that chest circumference and stature could be substituted for trunk volume and limb length in Viola's indices, used the ratio $\frac{\text{chest circumference}}{\text{stature}}$ as an anthropometric index.

They correlated the index with intelligence, efficiency, neurotic manifestations such as anxiety and obsessional symptoms, and found all the correlations were in the realm of chance, the highest being + 0.23.

INVESTIGATIONS BASED ON KRETSCHMER'S TYPOLOGY

A great deal of research was stimulated by Kretschmer's theory of an association between body types and temperamental types. A number of these studies selected well-defined types as described by Kretschmer and compared them with respect to a variety of psychological attributes by various methods. Thus van der Horst (1916) and Kibler (1925) utilized

questionnaires, and their results confirmed the association between leptosomatic body build and schizothymic temperament on the one hand and pyknic body build and cyclothymic temperament on the other.

A series of investigations carried out by van der Horst (1916), Kibler (1925) and Enke (1928), indicated that persons of pyknic physique, compared with those of leptosomatic physique, were more easily distracted in reaction-time experiments, were able to remember a smaller number of differently coloured squares on a card given at a certain speed, were poorer in the tachistoscopic perception of nonsense syllables. In further experiments on the tachistoscopic perception of long unfamiliar words, leptosomatic individuals were found to use an abstractive, analytic dissociative method in which the total work was built up by reading successive letters and syllables and constructing the whole from the parts. Pyknic individuals on the other hand, tended to use a synthetic integrative method. Persons with athletic physique occupied an intermediate position in the results of these tests. There is also evidence that pyknics tended to respond predominantly to colour in tachistoscopic experiments, and also tended to react to colours on the Rorschach test.

Lindberg (1938) reviewing the relevant literature concluded that the evidence indicated that persons of pyknic physique had a distinct tendency towards colour reactivity, whereas schizothymes and leptosomatics showed a distinct tendency for form reactivity. Lindberg (1938), using his own special tests, was able to demonstrate that manic-depressives had a greater tendency to colour reactivity and schizophrenics a greater form reactivity. Using Strömberg's index, he was able to demonstrate significant relationships between pyknic body build, manic-depressive illness with a greater tendency to colour reaction on the one hand, and between leptosomatic body build and schizophrenic illness and form reactivity on the other. His evidence suggests, but not conclusively, that pyknics differ significantly from leptosomatics in colour-form reactivity. The work of Keehn (1953) has thrown doubt on the interpretation of the tests used as being measures of "colour-form reactivity."

Misiak and Pickford (1944) found that leptosomes react more to mental and physical stimuli on the psychogalvanic reflex and are more persevering and have a lower tendency to perseveration than pyknics. Smith and Boyarsky (1943) found that leptosomatic individuals have a higher tempo (as measured by tapping rate) and also a quicker reaction-time. Kretschmer (1941) showed that leptosomes had a more sudden onset of fatigue on the ergograph, and also showed more sudden and variable pressure in writing. Klineberg, Asch and Block (1934) compared a number of psychological tests on groups of leptosome and groups of pyknic subjects. Tests included

cancellation of letters, intelligence tests, and tests of emotional adjustment and six tests specially designed to measure alleged characteristics of the two opposed constitutional types. They found no statistically significant differences between leptosomes and pyknics in these tests.

Similarly, Pillsbury (1939) and Kraines (1938) found no evidence to support Kretschmer's theory in a study of introversion-extraversion measured by personality inventories and physique measured by body-build indices.

More recently, Brattgard (1950) studied the relationship between personality attitude and physical make-up in a series of 1,000 patients attending a psychiatric clinic. This study is of special interest because the ratings of personality attitude had been made some time before the assessment of body build, and were not initially carried out with the intention of determining psychophysical correlates. He used Strömberg's index to assess body build, which was used for comparison with ratings previously made regarding patients' syntonetic, psychasthenic and hysterical attitudes. He found that syntonetic attitudes were associated with a pyknic physique, whereas psychasthenic attitudes were associated with leptosomatic physique.

Thus the results of investigations carried out to test Kretschmer's hypothesis of an affinity between personality and physical type are not all in agreement; some provide confirmation and others none.

FACTORIAL STUDIES OF THE RELATIONSHIP BETWEEN PHYSIQUE AND TEMPERAMENT

1. *Children*

Burt (1938), in a study of physique and temperament in schoolchildren, found that there were comparatively low correlations between stoutness and cheerful emotions on the one hand and between thinness with inhibitive and repressive tendencies on the other. In adults he found that leptomorphic body build tended to be associated with repressive and introvertive temperament and euryomorphic body build with depression. Burt (1949), in a study of four hundred and fifty-seven boys aged 11 to 13 years utilized the method of subdivided factors and found that the leptomorphic factor included two subfactors, one for limb length and the other for trunk length. The pyknic factor also had two subfactors, one for transverse and the other for sagittal measurements. He carried out a similar analysis of temperament and his results, together with physical type correlates, are shown in Table IX.4.

2. *Adults*

Body-build indices derived from factorial analysis of physique were used for studying relationships between

TABLE IX.4

CLASSIFICATION OF PERSONALITY AND PHYSICAL CORRELATES BY ORTHOGONAL SUBDIVIDED GROUP FACTORS (BURT, 1949)

Factor	Designation	Attribute of disposition	Body size, physical types and subtypes
I	General factor of all round emotionality	Less emotionality	1 Small body size or 2. Pyknic—obese subtype
		More emotionality	Thin and slender physique (Leptomorph)
II	Extraversion versus introversion	Extraversion	1. Large body size 2. Pyknic—eurymorphic subtype
		Introversion	Leptomorphic physique
III	Euthymic versus dysthymic	Euthymic	Broader eurymorphic physique
		Dysthymic	Leptomorphic physique

physical type and personality and neurosis in adult men by Rees and Eysenck, first in a group of four hundred soldiers (Rees and Eysenck, 1945) and subsequently in a further group giving a total of one thousand soldiers (Eysenck, 1947). Physique was assessed by the Rees-Eysenck body-build index for men as already described.

Rees (1950) carried out a similar study in a group of four hundred women service patients suffering from

TABLE IX.5

	Lepto- morphs (150) per cent	Meso- morphs (730) per cent	Eury- morphs (120) per cent

Schizoid seclusive	39	32	31

neurosis, utilizing a new regression equation for classifying body build in women derived from factorial analysis. Table IX.5 gives a summary of the findings, given as percentages, in the male group, and Table IX.6 the results for the female group. It should be emphasized that the clinical ratings and assessments were made quite independently of the assessment of physique, and were part of the routine investigation and assessment by the medical staff of all patients admitted to Mill Hill Emergency Hospital. The results obtained in both male and female adult groups are very similar. Eysenck (1944) had previously found from a factorial study of neurotic symptoms and manifestations, that there was a dichotomy of clinical types into hysteria and dysthymia. Inspection of Tables IX.5 and IX.6 shows that in men and women, leptosomes tend towards dysthymic symptoms and traits, whereas eurymorphs tend towards hysterical traits and symptoms. Comparison of items relating to the introversion-extraversion dichotomy of Jung, and the schizothymic-cyclothymic dichotomy of Kretschmer (1934), shows that leptomorphs have a greater tendency to introversion or schizothymic tendencies, whereas eurymorphs tend to be more extraverted and cyclothymic. There is also evidence that leptomorphs tend to have a higher incidence of somatic manifestations of emotional tension and autonomic dysfunction than eurymorphs.

The results are similar to those found by Sandford *et al.* (1943) in normal children. Their tall-narrow type was found to be associated with autonomic dysfunction, good intelligence test results, satisfactory school progress and also with guilt feelings, remorse and other features indicative of dysthymia. Their wide-heavy type, on the other hand, correlated negatively with autonomic dysfunction and positively with secure feelings and lively self expression.

Our findings of an association between eurymorphs and extraverted and cyclothymic tendencies and between leptomorphs and introverted and schizothymic tendencies, lends support to Kretschmer's theory of an affinity between body build and personality type. The higher incidence of symptoms of autonomic dysfunction in leptomorphs corresponds to the results of a study "Physique and Effort Syndrome" by Rees (1945) in which it was found that, as a group, effort syndrome patients were more leptomorphic than normal controls, and the leptomorphic patients tended to have a lifelong history of symptoms of autonomic dysfunction in contrast to the eurymorphic effort syndrome patients in whom exogenous rather than constitutional factors were important.

STUDIES UTILIZING SHELDON'S SOMATOTYPES

Sheldon (1942) calculated correlations between a large number of psychological traits and found that

TABLE IX.6

	Leptomorphs (60) per cent	Mesomorphs (263) per cent	Eury-morphs (77) per cent
1. <i>Age</i>			
16-20	12.2	17.5	20.2
21-25	61.1	51.2	45.9
26-30	10.7	19.6	24.3

Depression, moderate and severe	52	41	33
Irritability	54	44	37
Diagnosis: anxiety state, acute, severe	14	10	8
Diagnosis: anxiety state (all types)	60	59	51.3
3. <i>Personality</i>			
Marked schizoid personality	6.7	7	2.7
Very touchy and suspicious	7	6	1.5
Weak, dependent	89	55	46
Narrow interests	63	52	54
Inert, apathetic	15	6	9
Markedly cyclothymic	2.2	7	8.1
Hypochondriasis	37	27	25
4. <i>Autonomic dysfunction</i>			
Autonomic symptoms (palpitations, sweating, etc.)	49	44	40
Effort intolerance	65	62	55
5. <i>Miscellaneous</i>			
Duration of illness more than 1 year	40	45	27
Positive family history of marked neurosis	30	33	21
Childhood neurotic symptoms	48	43	42
Backward in elementary school	5	6	13
Good past physical health	57.7	71.7	22.9
Vocabulary test above average	22	22	14
Matrices test above average	13	10	12

they tended to form three clusters in which traits showed positive intracorrelations but had negative correlations with traits of the other groups. He considered these three groupings to be indicative of three primary components of personality which he termed viscerotonia, somatotonia and cerebrotonia. Viscerotonia is characterized by relative love of comfort, pleasure in digestion, greed for affection and approval and the need of people's company when in trouble. Sheldon states that the personality of viscerotonics seems to centre around the viscera. Somatotonia is

characterized by an assertive posture, energy, a need of exercise, directness of manner, unrestrained voice and a need for action when in trouble. Cerebrotonia is characterized by restraint in posture, quick reaction, socio-phobia, inhibited social address, vocal restraint, youthful intentness and a need of solitude when troubled.

In a group of two hundred university men between the ages of 17 and 31 years, Sheldon (1942) found correlations between components of physique and temperament as follows: endomorphy and viscerotonia + 0.79, mesomorphy and somatotonia + 0.82, ectomorphy and cerebrotonia + 0.83. These correlations are much higher than those reported by other workers in the field of physical temperamental relationships.

Sheldon's (1942) findings have been criticized because of the possibility that a "halo" effect might have influenced the reported correlations as both physique and temperament were rated by the same observer.

Davidson, McInnes and Parnell (1957) investigated body build in a group of one hundred seven-year-old children with the object of determining what relationships existed between somatotype and psychiatric symptoms and psychological attributes. They found that symptoms of anxiety and emotional unrest were associated with ectomorphy. Among girls significant positive correlations were found between ectomorphy and meticulous, fussy and conscientious traits of personality. The results on the Rorschach test showed that ectomorphs tended to be associated with movement responses and endomorphs with colour responses, but the correlations were not statistically significant. In general the correlations between somatotype and psychological attributes were of a low order and none approached the high correlations reported by Sheldon (1942) between somatotypes and temperamental characteristics.

Parnell (1957) compared somatotype distribution in four hundred and five healthy students with that in a group of two hundred and eight students who were advised by their general practitioners to seek psychiatric care. It was found that the linear person with poor muscular development, and below average in fat, was six times more common in the patient group. The averagely fat, rather muscular short man was found to be five times more common in the healthy group than in the patient group.

Wittman, Sheldon and Katz (1948) studied the relationships between somatotype and psychiatric attributes based on Wittman's check-list. The first psychiatric component (designated manic-depressive) correlated 0.54 with endomorphy, 0.41 with mesomorphy, and - 0.59 with ectomorphy. The second psychiatric component (paranoid) correlated - 0.04 with endomorphy, 0.57 with mesomorphy, and

— 0.34 with ectomorphy. The third psychiatric component (hebephrenic) had a correlation of — 0.25 with endomorphy, — 0.68 with mesomorphy, and + 0.64 with ectomorphy. Sheldon *et al.* (1949) also attempted to correlate neurotic behaviour reactions with somatotype. Hysteria was found to be associated with ectopenia, neurasthenia with lack of development of mesomorphy, and psychasthenia with lack of development of endomorphy.

Humphreys (1957) severely criticized Sheldon's methods and states that the evidence provided by Sheldon supported not more than two independent (but not necessarily valid) types of temperament.

Child and Sheldon (1941) studied the correlation between somatotype and tests of verbal and numerical aptitude, ascendance-submission, and masculinity-femininity. The correlations were uniformly low, the highest being 0.21. Fiske (1944) found no significant correlation between somatotype and intelligence test score in a group of one hundred and thirty-three boys ranging in age from 13 to 17. Tanner (1957) refers to an investigation in which a group of boys aged 17 from an English boarding school were somatotyped by different observers from those assessing temperament by means of Sheldon's shortened scale. The results provided little to support Sheldon's claims for high correlations between somatotype and temperament. In so far as they go, the results of these studies are in good accord with those of Rees-Eysenck and of Burt, quoted above.

STUDIES BASED ON LINDEGARD'S METHOD OF ASSESSING PHYSIQUE

Lindegard and Nyman (1956) attempted to correlate personality attributes and physique in a group of three hundred and twenty men. Personality was assessed and rated according to the system of Sjöbring and physique by Lindegard's (1953) method.

The results showed that the muscle factor correlated positively with "validity" (i.e. expansivity and self confidence versus unobtrusiveness). Both muscle and fat factors were negatively correlated with "stability" (i.e. emotional warmth versus emotional coolness and sophistication and proficiency of motor pattern).

Lindegard and Nyman (1956) considered that the findings of Rees and Eysenck (1945), that subjects of tall, narrow body build have a high vocabulary score, was compatible with their own findings of a significant negative correlation between vocabulary score and muscularity in their series. It is interesting that Wretmark (1953), in a study of personality in peptic ulcer patients and normal controls, using Sjöbring's system for assessing personality and anthropometric indices for assessing body build, found that stability was the only factor to be correlated with body build. He found that substable individuals were relatively

wide-heavy and that superstable individuals tended to be tall-narrow in body build.

Lindegard and Nyman's (1956) results were not wholly in conformity with either those of Kretschmer (1921) or those obtained by Sheldon (1942) regarding the physical make-up of the cyclothymic and viscerotonic individuals, but the criteria and methods used differ so widely that it is impossible to make a satisfactory comparison of results.

BODY SIZE IN RELATION TO PERSONALITY AND NEUROSIS

The significance of body size as opposed to bodily proportion, has received little attention by investigators of physical-psychological correlates.

1. *Index of Body Size*

Rees and Eysenck (1945) found that the following measurements had the highest saturation with the general factor of body size and were therefore likely to be the most useful measurements for the construction of size indices—

- (i) Suprasternal height
- (ii) Bicristal diameter
- (iii) Stature
- (iv) Transverse chest diameter

Stature and transverse chest diameter were the measurements chosen as these measurements had already been taken on a group of 1,100 soldiers, successively admitted to Mill Hill Emergency Hospital, and on whom detailed psychological data recorded independently were also available. The product of these two measurements gives a convenient index of body size. The mean stature for the group of 1,100 soldiers was 172.067 cm with a standard deviation of 6.69, and a coefficient of variation of 3.38. The mean transverse chest diameter was 27.63 cm with a standard deviation of 1.902 and a coefficient of variation of 6.98. It will be seen that the coefficients of variation of these two measurements differ considerably and therefore absolute measurements could not be used for inclusion in an index of body size. Each measurement was, therefore, converted to standard measure, that is expressed in terms of standard deviation, and the product of stature and transverse chest diameter expressed in standard measure was calculated on each patient. From Fig. 9.7 it will be seen that the index values are distributed along a normal frequency (Gaussian) curve with some positive skewness. The frequency curve shows no evidence of bimodality or multimodality, which would suggest the existence of disparate types of body size, but a continuous variation from one extreme to the other.

For the purposes of investigation it will be necessary to choose arbitrary points for classification of the group. The demarcation points chosen were one

standard deviation above and below the mean, dividing the group into three classes—

1. Small size or microsomatics, individuals of index values of 1,683 and less.
2. Medium size or mesomatics, comprising individuals with index values between 1,684 and 3,110.
3. Large size or macrosomatics, individuals with index values 3,110 and over.

FIG. 9.7. FREQUENCY DISTRIBUTION CURVE OF THE BODY SIZE INDEX IN A GROUP OF 1,000 SOLDIERS

An item sheet on each patient in the hospital had already been completed quite independently of physical assessment and contained over two hundred items relating to social data, personal and family history, personality, symptomatology, etc. The distribution of various items for the microsomatic, mesosomatic and macrosomatic groups is given in Table IX.7. The significance of the differences in percentage incidence between the groups was tested by the critical ratio method and only ratios of 2 and over were taken as significant.

2. Body Size, Intelligence and Personality Traits

The results indicate that the microsomatic group tends to be lower in level of intellectual capacity than the macrosomatic group, as shown by the significantly higher proportion of individuals below average in intelligence in both progressive matrices and the vocabulary tests. Further evidence of a lower intellectual level in the microsomatic group is the higher proportion of individuals who failed to proceed beyond the second class from the top at primary school and the higher proportion of individuals who had unskilled

Slight neurosis	44.9	48.7	48.7

civil employment. The microsomatic group tends to be of inadequate personality make-up, as shown by the higher incidence of weak dependent, anxious and hypochondriacal traits of personality with narrow interests and hobbies. The macrosomatic group showed, in addition to greater body size, better musculature, tone and posture.

3. Body Size and Neurosis

Both microsomatics and macrosomatics show evidence of predisposition to a neurotic breakdown, as shown by the high incidence of childhood symptoms, by previous general behaviour indicative of a clear predisposition of mental illness and by the high proportion of individuals rated as being of unstable personality. The predisposition to neurosis in macrosomatics expressed itself differently from that in microsomatics in that they tended to be more active, rebellious and aggressive.

In symptomatology and psychiatric diagnosis, there was a general similarity between the three groups, a notable difference was the higher incidence of depression as a symptom in the macrosomatic group. The mesosomatic group usually occupies an intermediate position in the percentage incidence of those traits which show statistically significant differences.

Rees (1950), discussing these findings, concludes that the general picture emerging from the study is that neurotics of large body size tend to be more active, having more stable personalities, better musculature, a higher intellectual level and a better prognosis for return to military duties.

These findings are what one might expect on general considerations. The small person, apart from his constitutional make-up (i.e. his physical, psychological

and physical attributes, determined in main, genetically), might react in many ways to his smallness as Adler has indicated. A person may over-compensate for his smallness by assuming aggressive and dominating traits, or he may accept a more normal degree of compensation, or he may react by developing inferiority feelings. In our study we find little evidence

that neurotics of small body size tend to over-compensate by aggressive or dominating behaviour. It might be contended that a socially acceptable degree of compensation in this direction might have had a salutary affect in preventing neurosis. In fact, however, we find evidence of the opposite tendency. If anything, that is acceptance with feelings of inferiority, as shown by the high incidence of weak, dependent and timorous personalities, anxious highly strung types of personality (61 per cent), hypochondriacal tendencies (27 per cent), and the lack of such possible signs of over-compensation such as rebellious and aggressive tendencies (13 per cent) or conspicuous energy and activity (4.5 per cent).

While it is clear that there was little evidence of over-compensation for any feelings of physical inferiority in the micro-somatic group, it would not be safe to assume that lack of such compensation, and the adoption of a defeatist attitude, and the surrender to feelings of inferiority, had played an important role in the development of neurosis in the micro-somatic group, although the adherent school would no doubt assume this to be the dominant factor. An aetiological study of this group showed that multiple aetiological factors were responsible, and that there was evidence of a high degree of assumed predisposition to neurosis or neurotic constitution, as defined by Slater (1943), in all groups as shown by the high incidence of clinically abnormal personality, positive family history, and the incidence of childhood neurotic symptoms.

It is interesting to note that the psychological correlates of body sizes are different from those associated with body type. Whereas the extreme types of body size show significant differences in the incidence of certain personality traits, the extremes of

body type, the curymorph and ectomorph, tend to be associated with hysterical and anxiety reactions respectively, which show no significant differences in groups classified according to body size.

Bodily Disproportions in Relation to Dominant Personality Traits

Seltzer (1946) described an investigation on a group of two hundred and fifty-eight Harvard undergraduates by means of anthropometric measurements and body-build indices. He paid particular attention to body disproportion, which he defines as values of an index which are extremely divergent from the mean, usually in one direction. Examples of such disproportions are a combination of wide shoulders and thin legs, or very broad hips relative to shoulder width, a very flat chest relative to shoulder width, very broad hips relative to chest breadth, broad face relative to chest width, etc. The term disproportion must not be confused with the term dysplasia. The term "disproportion" was not intended to carry a stigma of abnormality, and the ratios are simply normal deviates from the mean of the group as a whole. Seltzer (1946) found that disproportions were more frequent among individuals of unstable autonomic functioning than in the series as a whole. Individuals who were extremely linear were virtually twice as frequent in this trait grouping. In basic personality the less well integrated group was distinguished by a significant excess of individuals with extremely linear body builds, with flat chests relative to their shoulder breadths, and with small calf circumference relative to their shoulder breadths. He found significant excesses of one or more disproportions over the total series frequencies in the following trait groupings: unstable autonomic functions; less well integrated; mood fluctuations; sensitive affect; bland affect; meticulous traits; inhibited; self-conscious and introspective. Significant deficiencies, on the other hand, of one or more disproportions over the total series frequencies occurred in the following traits: well integrated; vital affect; practical organizing; humanistic and pragmatic.

The first list contains trait groupings indicating lesser stability and integration together with sensitivity; a complexity of the personality, with lower capacity for making easy social adjustment. The second list is diametrically opposite to the first. Here the traits are suggestive of stability, good integration and ease of making adjustments. Seltzer (1946) found that disproportions were most common in strong ectomorphs and least common in marked endomorphs and marked mesomorphs. He considered that the disproportions were constitutional and possibly indicated a genetic element in the determination of personality and behaviour.

INTELLIGENCE LEVEL AND PHYSICAL STATUS

Psychologists and educationalists have for many years tried to discover relationships between physical attributes and level of intelligence with the aim of obtaining objective aids for the assessment of the latter.

1. *Isolated Morphological Variables and Intelligence*

Investigations have been carried out to ascertain possible relationships between intelligence level and isolated anthropometric measurements of the skull and the body. Mead (1914) studied the relationship, in children, between height and weight and general intelligence and found that the lower the intelligence the more checked is physical growth, this being more evident with height than with weight. Doll (1916), from a study of three hundred and thirty-three children, reported a correlation of + 0.31 between stature and mental age and one of + 0.41 between standing height and mental age. Wheeler (1929) studied anthropometric data of the Harvard growth study on one hundred and fifty-four mentally dull boys and one hundred and nineteen mentally dull girls and found consistent, though slight, differences in stature, sitting height, sternal length, leg length, trunk length and bicristal diameter, which were smaller in the mentally dull groups than in normal children.

Somerville (1924), in a study of one hundred college students, found a correlation between intelligence and stature of + 0.1, sitting height + 0.13, weight + 0.1, chest girth + 0.01. None of the correlations was statistically significant.

Brooks (1928) studying groups of school and college pupils, reported that correlations between weight and intelligence varied between - 0.08 and + 0.31, and concluded that the results pointed to a zero correlation between weight and intelligence in adolescence.

Pearson and Moul (1925) conducted an elaborate biometric study of six hundred and sixteen boys and five hundred and eighty girls of Jewish origin, resident in London, and found a negligible correlation between estimated intelligence and height and weight.

Lee, Lorenz and Pearson (1903) studied honours and pass men at Cambridge using scholastic standing as a criterion of intelligence. They found a non-significant correlation between weight and intelligence of + 0.0502.

The product moment correlations between anthropometric measurements and intelligence level as measured by the Raven's progressive matrices in a group of two hundred soldiers is given below. All the correlations are low and none is statistically significant. The consensus of results there indicates a zero correla-

TABLE IX.11

Variate	Pearson product moment correlation coefficient
Stature	+ 0.111

Chest circumference at inspiration	+ 0.051
Chest circumference at expiration	+ 0.101
Hip circumference	+ 0.177
Weight	+ 0.172

tion between absolute anthropometric measurements and intelligence level.

2. *Physical Type and Intelligence Level*

Viola (1933) regarded the macrosplanchnic type as tending to be lower in intelligence level than the microsplanchnic and normosplanchnic types. In keeping with this, Naccarati (1921) found that bright children, during the growth period, tended to micro-splanchny in contrast to less bright or dull children. In other investigations Naccarati (1924), Naccarati and Garratt (1924), found that correlations between $\frac{\text{height}}{\text{weight}}$ index and intelligence varied between + 0.1 and + 0.44, the average of thirteen correlation coefficients being + 0.256.

Stalnaker (1923) found that there were correlations of + 0.8 and + 0.3 between the $\frac{\text{height}}{\text{weight}}$ index and intelligence in groups of one hundred and fifty school pupils, whereas Heidebreder (1926), who studied a group of one thousand students and adequately controlled the data for sex distribution and reliability of intelligence tests, found that evidence pointed to a zero correlation.

Sheldon (1927) investigated four hundred and thirty-four college freshmen by means of Naccarati's index of body build and found that its correlation with intelligence rating was + 0.14 \pm 0.03. Garratt and Kellogg (1928) also used the morphological index of Naccarati, calculated from photographs, and intelligence measured by psychological examination for college freshmen in a group of two hundred and six individuals and found a correlation of + 0.07 \pm 0.05.

Sheldon (1942) found that the correlations between intelligence quotient and morphological types were low, but there were correlations of $+0.48$ between "aesthetic intelligence" and mesomorphy and ectomorphy.

Parnell (1955) studied groups of three hundred and seventy-one boys and four hundred and twenty-one girls aged 11 and concluded that the less muscular children tended to pass the grammar school examination. He found that linear subjects with more than average fat for their weight were best at examinations.

He found that all-rounders in university students, viz. those who played games and got a first-class degree, were somewhat more muscular. Endomorphic ectomorphs obtained a significantly high proportion of first-class honours (35 per cent). Mesomorphs (65 per cent) obtained second-class honours. Ectomorphs were found to enjoy the widest range of possibilities for better or for worse. Mesomorphs were most consistent in obtaining a good level of performance with first- or second-class honours. Endomorphic ectomorphs who did exceptionally well in finals, received only a near average proportion of awards on entry.

BODY-BUILD INDICES AND INTELLIGENCE LEVEL

The following indices (*see* appendix to this chapter) were correlated with Progressive Matrices score in a series of two hundred successive soldiers admitted to Mill Hill Emergency Hospital: Morphological index $+0.118 \pm 0.069$, Pignet index $+0.161 \pm 0.07$, Brugsch index $+0.061 \pm 0.07$. All of these correlations are small and none is statistically significant.

A series of nine hundred and seventy-six successive soldiers admitted to Mill Hill Emergency Hospital were classified into leptomorph, euryomorph and mesomorphic physical types by means of the Rees-Eysenck index; 33 per cent of the leptomorphs were above average, that is Grades 1 and 2, compared with 25 per cent of the euryomorphs. 29 per cent were below average in the leptomorphs compared with 34 per cent in the euryomorphs. The mesomorphs were intermediate. On the vocabulary scale, 37.5 per cent of leptomorphs were above average, compared with 22 per cent of euryomorphs. The difference of 8 per cent in the above average intelligence grades in the Matrices tests is not statistically significant. The difference of 15.4 per cent in the above average intelligence grades in the vocabulary test is statistically significant at the 5 per cent level, and is in conformity with Lindegard's (1956) results.

In conclusion we may say that the correlation between physique and intelligence is so low that a knowledge of a person's physical status will be of no value in the prediction of intelligence in the individual case.

PHYSIQUE IN RELATIONSHIP TO DELINQUENCY AND CRIMINALITY

Investigators have, for many years, attempted to ascertain whether any significant relationships exist between physical type and various morphological characteristics and delinquency and criminality.

Lombroso (1911) studied morphological anomalies in criminals and founded the doctrine that the criminal, as found in prison, was an atavistic anomaly presenting morbid physical stigmata.

In more recent years, interest has turned away from the question of physical stigmata to other aspects of body build. Hooton (1939) studied 17,000 prison and reformatory inmates and reported significant differences in various body measurements between persons convicted of different types of crime. Among his findings were that both the shortest sixth and the heaviest sixth of the group headed the list of crimes for rape, sex offences and assault, but were lowest in murder, whereas the contrasting group consisting of tall and slender criminals had the highest incidence of murder and robbery, but the lowest or next lowest in crimes such as burglary, assault, rape and other sex offences.

Glueck and Glueck (1950) compared a group of delinquents, consisting of five hundred boys aged 11 to 18 years, with five hundred non-delinquent controls, matched for age, intelligence, racial origin and residence in under-privileged neighbourhoods. They compared anthropometric measurements and somatotype distribution and found that there was little difference in general body size, but that the delinquent group was considerably more mesomorphic and less ectomorphic than the non-delinquent group.

Sheldon *et al.* (1949), described a study of two hundred delinquent youths who were somatyped according to Sheldon's system and were compared in respect of somatotype distribution with 4,000 college students. They found that the sample of delinquents differed sharply from the college somatotype distribution, having a distinct and heavier massing in the endomorphic-mesomorphic sector. They found that mesopenes were, on the whole, rare. Ectomorphs were rare and also ectomorphic-mesomorphs in comparison with endomorphic-mesomorphs. As a generalization, they concluded that the two hundred delinquent youths were decidedly mesomorphic and also decidedly ectopenic, but that there appeared to be no strongly defined tendency, either way, with regard to endomorphy.

Epps and Parnell (1952) studied a group of one hundred and seventy-seven young women, between the ages of 16 and 21, undergoing Borstal training. Anthropometric measurements were carried out on the delinquent group and compared with a group of one hundred and twenty-three university women aged between 18 and 21. They found that delinquents were heavier in

body build and were more muscular and fat. In temperament they showed a predominance of somatonia and viscerotonia. All these results are in good agreement with the Rees-Eysenck finding of a correlation between extraversion and eury-morph body build, and Eysenck's theory linking extraversion with psychopathy and criminality. (Cf. also Chapter 12.)

PHYSIQUE AND TYPE OF OCCUPATION

A good review of this subject is given by Damon and MacFarlane (1955), who point out that the first systematic study of physique of workers was carried out by Quetelet (1835), a Belgian statistician, who introduced the term anthropometry. Cathcart *et al.* (1935) found differences in strength and physique among individuals in different occupations. For example, they found that transport workers were taller, stronger and heavier than clerical workers. Coerter (1929) classified individuals in various occupations according to Rostan's constitutional types and found that locksmiths, transport workers and shoemakers tended to be of muscular type, and that lithographers, telegraphists, cabinet makers and weavers tended to have the respiratory type of body build.

Garn and Gertler (1950) found that a group of research workers was significantly less endomorphic, less mesomorphic and more ectomorphic than a group of factory workers in the same establishment.

MacFarlane (1946, 1953) and Damon (1935) found that civilian air pilots were smaller, heavier and stockier and generally more mesomorphic than the general population. Damon (1945) found that the more successful war-time aviators were more mesomorphic and masculine, with large chest girth, both relative and absolute to stature. Damon (1955), in a further study, utilizing techniques which included classical anthropometry, Seltzer's (1946) disporportions and an approximation of Sheldon's somatotyping, found that the more successful flyers were, on the average, more mesomorphic and masculine.

Woods, Brouha and Seltzer (1943) found that there was a significant association between masculinity of body build and high ratings for excellence as an officer. Seltzer (1945), in a study of two hundred and fifty-eight students, found significant relationships between choice of faculty and the masculinity component of physique. He found that in those individuals with low ratings of masculinity, there was a prediction towards arts and philosophy. Parnell (1953) found that students of engineering, dentistry and medicine were more mesomorphic and less ectomorphic than students of physics and chemistry. Tanner (1955) criticizes this work on the ground that many of the somatotypes have been obtained in an unconventional and an unwarranted manner, and also for its sketchy

statistical treatment. Tanner (1955) compared the physique of two hundred and eighty-seven officer cadets, one hundred and seventy-one Oxford University students, and one hundred and sixty-two medical students. He found that the officer cadets were much more mesomorphic and somewhat lower in endomorphy and ectomorphy than Oxford University students. The medical students were in between the other two groups in mesomorphy, but in endomorphy they were the lowest group. Both student groups exceeded the officer cadets in ectomorphy, but did not differ between themselves. In considering the possible determinants of these associations, Tanner (1955) discussed the possible role of (1) social background and early environmental effects; (2) self-selection by the individuals of their type of career; (3) institution selection; (4) physical changes after entry to the institution. He concluded that the type of occupation, social origin or educational attainment could not explain the differences and that self- and institutional-selection were undoubtedly the main factors involved.

In conclusion, one might say that the evidence suggests that there are tendencies for different types of physique to be associated with certain psychological characteristics, including personality traits and various neurotic symptoms, but the majority of investigations do not report any correlations as high as those reported by Sheldon (1942).

The available evidence suggests that the correlations between physical characteristics and personality traits, intelligence and neurotic symptomatology, although often statistically significant, are nearly always too small to be trusted for the needs of diagnosis.

Physique and Susceptibility to Disease

Physicians have, from time immemorial, attempted to establish correlations between constitutional attributes and tendency to develop various diseases. The dichotomy in physique described by Hippocrates (viz. the *habitus pthicus* and the *habitus apoplecticus*) was followed by Galen's detailed differentiation of physical types associated with specific temperamental qualities and disease susceptibility.

John Hunter (1728-1793) was a strong proponent of the theory that susceptibility to disease varied with the type of constitution, but it was nearly a hundred years after his death before serious study of the relationships between morphological characteristics and disease was carried out by Beneke (1881) in Germany and Di Giovanni (1919) in Italy.

Interest in the constitutional aspects of medicine was relegated to the background as knowledge of bacteriology and pathology increased. In recent years greater interest has again been taken in the constitutional factors in disease, and this has been greatly

stimulated by the marked prevalence at the present time of the so-called stress diseases or psychosomatic disorders in which constitution appears to play an important role.

There is a paucity of scientifically satisfactory investigations into the relationship between physical constitution and various diseases. Failure to utilize random samples of the disorder under consideration, and lack of satisfactory control groups and inadequate statistical evaluation of data, are some of the reasons for slow advance in this field.

PHYSIQUE AND PSYCHOSIS

Although Esquirol (1876) noted that the strong robust type had a tendency to be associated with an acute course of psychosis, with crises, whereas the lymphatic type tended to have a more chronic deteriorating course, Kretschmer (1921) must receive the main credit for elucidating relationships between physical type and psychotic type. The publication of his theory of a biological affinity between pyknic physique and manic-depressive psychosis on the one hand, and between schizophrenia and leptosomatic, athletic and certain dysplastic physiques on the other, stimulated research in all parts of the world.

The results of some of the investigations provide strong support for Kretschmer's hypothesis, others support it only in part, whereas some do not support it at all. Among the authors whose results supported Kretschmer's hypothesis, are Sioli and Meyer (1922), Olivier (1922), Jacob and Moser (1923), Michel and Weber (1924), Nenckel (1924), Weissenfeld (1925), Wyrsh (1924).

The work of Wertheimer and Hesketh (1926) merits more detailed consideration. They studied body build in sixty-five male patients by means of an index, based on that of Viola, which had leg length as the numerator and transverse chest diameter, sagittal chest diameter and trunk length as the denominator. They found that among patients with low index values (indicating a pyknic physique) there was a predominance of manic-depressives, whereas among patients with high index values (indicating more narrow type of body build) schizophrenic psychosis predominated. Schizophrenic patients were found to be scattered over a wider variety of body types, but the greater number fell into the leptosomatic and athletic groups.

Only partial support for Kretschmer's theory was given by the results of Raphael, Ferguson and Searle (1928), who compared a number of anthropometric measurements and body-build indices on sixty schizophrenics and sixty manic-depressives and Clegg (1935), who studied one hundred manic-depressives, one hundred normals and one hundred schizophrenics. Burchard (1936), who studied four hundred and seven male patients, including a group of one hundred and

twenty-five schizophrenics and a group of one hundred and twenty-five manic-depressives, found that when the group was classified by impression into pyknic, athletic and leptosomatic types, there was an association between pyknic type and manic-depressive psychosis and between the leptosomatic type and schizophrenia. Comparison of anthropometric indices showed that transverse and sagittal chest diameters, bicristal diameter and certain body-build indices, showed statistically significant differences pointing to a more leptosomatic physique in schizophrenic patients. He found, however, that age influenced physical type. A more detailed analysis of the age factor on Burchard's data, carried out by Anastasi and Foley (1949), showed that there was a definite tendency towards a more pyknic body build with advancing age in each psychotic group as well as in the entire group. They found a correlation of -0.256 between age and body-build index values for the entire group. The findings indicate that some of the difference observed between the two psychotic groups could be attributed to age, and suggest that the relationship between body build and types of psychosis, as indicated by the results of this study, is rather slight.

Farber (1938) studied the stature, weight and $\frac{\text{height}}{\text{weight}}$ ratio in eighty-one schizophrenics and eighty manic-depressive patients and considered that the tendency for pyknic type of physique to increase with age, and the greater tendency for physical deterioration in schizophrenia, would weaken if not entirely invalidate Kretschmer's theory. Connolly (1939) carried out an anthropometric study of one hundred male psychotic subjects and found that schizophrenic patients (excluding paranoid schizophrenics) were below the average for all measurements and paranoid schizophrenics and manic-depressives were above the average in body measurements. Using the Pignet index, he found that there was a preponderance of the leptosomatic type in the schizophrenic group and of the pyknic type in the paranoid schizophrenic and manic-depressives. This work therefore supports Kretschmer's theory, and in addition finds that paranoid schizophrenics are more akin to manic-depressives in bodily *habitus* than to other types of schizophrenia.

Cohen (1940), in a study of forty-seven English male patients, found a significant correlation of 0.413 between the combined weighted measure of arm length, leg length, waist circumference and manic-depressive psychosis and schizophrenia. In a group of fifty-one female Jewish patients, he found a significant correlation of 0.557 between a combined weighted measure of chest depth, pelvic breadth and manic-depressive psychosis and schizophrenia, thus supporting Kretschmer's theory. Betz (1942), in a careful study of the

physical status of one hundred and ninety-three schizophrenic women, found that schizophrenes were small in general size, and showed a greater proportion of persons of asthenic build and a smaller proportion of persons of pyknic build than normal and non-schizophrenic groups. These findings were obtained both when the impressionistic method of assessing physical types and when anthropometric measurements were used.

Moore and Hsu (1946) carried out a factorial analysis on physical measurements in groups of psychotic patients and found significant relationships between body build and psychotic types at the 1 per cent level for the following relationships—

(a) Non-paranoid schizophrenics were below both manic-depressives and paranoid schizophrenics in the girth factor and were higher in the leptosomia factor and particularly high in the ratio of leptosomia, girth and robustness.

(b) Paranoid schizophrenics differed from manic-depressives in a lower ratio between the robustness factor and the girth factor.

AN ANTHROPOMETRIC STUDY OF MANIC-DEPRESSIVE PATIENTS

Rees (1953) carried out detailed anthropometric investigation of forty-two patients suffering from manic-depressive psychosis and compared the group with a group of one hundred normal subjects and forty-nine schizophrenic patients. The manic-depressive group was found to be significantly smaller in stature, suprasternal height and biacromial diameter, and was significantly larger in sagittal chest diameter than the normal group.

The Strömngren index significantly differentiated the manic-depressive group from the normal group indicating that the manic-depressive group was significantly more euryomorphic in body build.

Comparison of the manic-depressive and schizophrenic groups showed that the anthropometric measurement showing the greatest difference was sagittal chest diameter. The manic-depressive group was also significantly larger in bicristal diameter, hip circumference and transverse chest diameter. Various body-build indices showed significant differences indicating a greater tendency to euryomorphic build in the manic-depressive group, these included

stature
sagittal chest diameter, the index showing the highest discrimination; the next was Strömngren index, followed by the following indices in order of degree of statistical significance of difference between the groups:
trunk length, Pignet index, $\frac{\text{trunk length}}{\text{sagittal chest diameter}}$, $\frac{\text{trunk length}}{\text{bicristal diameter}}$, the Boldrini index and the Morphological index. All

these indices, however, showed considerable overlapping and that the main differences between manic-depressive, normal and schizophrenic groups, were in the central tendency of a number of anthropometric measurements and body-build indices.

THE SIGNIFICANCE OF THE AGE FACTOR IN THE RELATIONSHIP BETWEEN PHYSICAL TYPE AND MANIC-DEPRESSIVE PSYCHOSIS

As both manic-depressive psychosis and euryomorphic physique tend to occur more frequently in middle age, the question arises whether the alleged affinity between the two could be attributable to this temporal coincidence. In view of the increased incidence of manic-depressive psychosis in middle age, it is likely that a random sample will have a relatively high mean age. This was found to be the case in Rees's group which had a mean age of 50.47 years. It is of interest to compare the mean age of other manic-depressive groups investigated to test Kretschmer's theory. The following are some examples: Wertheimer and Hesketh (1926) 39.3 years; Raphael, Ferguson and Searle (1928) 47.5 years; Farber (1938) 44.5 years; Connolly (1939) 47.9 years. Thus all these groups have a considerably greater mean age than Rees's normal and schizophrenic groups. When only the younger members of the manic-depressive group were considered, they were found to be more pyknic in body build than the normal group, but the difference only just approached statistical significance. It was concluded that the age factor plays some part in the affinity between manic-depressive psychosis and euryomorphic body build, but that it did not account for the entire association and did not completely invalidate Kretschmer's theory.

In view of recent researches which indicate that in adult life increasing age determines changes of physique, it is of the greatest importance that in future researches on body build in manic-depressive psychosis, the age factor should be strictly controlled. The present investigation provides some support for Kretschmer's hypothesis between pyknic *habitus* and manic-depressive psychosis, but the correlation is not by any means as high as suggested by Kretschmer.

AN ANTHROPOMETRIC STUDY OF SCHIZOPHRENIC AND NORMAL CONTROL GROUPS

In order to test Kretschmer's hypothesis of an affinity between schizophrenia and certain types of physique, Rees (1943) carried out a detailed anthropometric investigation of a random sample of forty-nine patients suffering from schizophrenia, and a control group of one hundred normal men of similar age distribution. The average age of the schizophrenic group was 28.75 years and did not differ significantly from that of the normal group (29.27 years). The

schizophrenic group was found to be significantly smaller than the normal group in the following measurements: stature, chest circumference, hip circumference, biacromial diameter, suprasternal height and symphysis height.

The schizophrenic group was also significantly more leptosomatic than the normal group, as was shown by statistically significant differences in the Morphological, Boldrini and Pignet indices. The biserial coefficient of correlation between leptosomatic build, measured by the Boldrini index, and schizophrenia, was 0.64 ± 0.06 .

Comparison of distribution of physical types objectively delineated by various body-build indices showed the schizophrenic group to have a lower percentage of persons of intermediate physique. The incidence of patients with euryomorphic body build did not differ significantly from the normal control group. The results correspond closely to those of Betz (1942) who carried out a careful study of the body build in a group of one hundred and ninety-three schizophrenic women and found that schizophrenics were smaller in general size and had a higher proportion of persons of leptosomatic body build than normal group.

BODY BUILD IN RELATIONSHIP TO TYPE OF SCHIZOPHRENIA

There is some evidence to suggest that paranoid schizophrenics tend to differ in physical constitution from catatonic, hebephrenic and simple types of schizophrenia. Connolly (1939) found that paranoid schizophrenics were above the average for all measurements, and were more pyknic in body build than the other types of schizophrenic patients. This was also borne out by the factorial studies carried out by Moore and Hsu (1946). The work of Mauz (1930), Kisselew (1931), Platner Heberlein (1932), Vanelli (1932), Langfeldt (1937) and Betz (1942), suggests that schizophrenics with a leptomorphic body build tend to have an early age of onset, show a greater degree of withdrawal, apathy and scattered thinking, whereas schizophrenics of euryomorphic body build tend to have a later age of onset, better preservation of personality, and better affective relations with the environment.

We have already seen that there is now considerable evidence that there is a tendency for pyknic body build to increase with age. The question arises therefore, whether the alleged association between paranoid schizophrenia and pyknic physique, and between leptomorphic physique and schizophrenia with an earlier age of onset, could be attributable largely or entirely to the age factor. There is a clear need for further research in this field utilizing diagnostic groups accurately matched for age, sex, socio-economic

status and investigated by adequate anthropometric and statistical methods.

BODY BUILD AND PROGNOSIS IN SCHIZOPHRENIA

Kalman (1953) found that the tendency to extreme deterioration during the course of a schizophrenic illness, was correlated with the presence of high asthenic and low athletic components of physique. He found that schizophrenics with the high athletic (mesomorphic) and low asthenic (ectomorphic) component in physique showed the relatively strongest resistance and were usually of the paranoid type of schizophrenia. He found, in agreement with the observations of Klein and Oppenheim (1952), that the pyknic component, although unrelated to differences in deterioration, was associated with a relatively poor prognosis. Kalman (1953) also found that concordant, monozygotic twins, without significant somatotypic differences, tended to have similar types of schizophrenia, developing usually at the same age and having a similar outcome. When there were differences in physique and physical development in such twins, there were usually differences in the age of onset as well as in the severity of clinical schizophrenic symptoms. In the smaller group of monozygotic twins, discordant for schizophrenia, it was found that, as a rule, if one twin remained completely free from schizophrenic symptoms, a definite difference was found in physical strength and body weight from early childhood consistently in favour of the more resistant twin.

Bleuler (1948) produced evidence in support of his hypothesis that certain types of schizophrenia show certain physical attributes related to endocrine abnormalities. He found, for example, a certain type of schizophrenia associated particularly with the acromegaloid type of *habitus*. This type is distinguished by having large hands, feet and body size and a tendency to irritability and periodic exaggeration of the sexual urge. This type was frequently found to be associated with familial incidence of schizophrenia, and appeared to exert a favourable pathoplasmic effect on the symptomatology of a co-existing schizophrenic illness. Schizophrenic illnesses associated with the acromegaloid *habitus*, were found by Bleuler (1948) to be characterized by a later onset and a particularly mild clinical course.

RELATIONSHIPS BETWEEN OTHER CONSTITUTIONAL ATTRIBUTES AND TYPE OF SCHIZOPHRENIA

The cardiovascular system studied both macroscopically and microscopically, has been extensively investigated in schizophrenic patients. Lewis (1936) reported that a hypoplastic circulatory apparatus was found consistently at autopsy in catatonic and hebephrenic types of schizophrenia. He found that the

heart was approximately one-third smaller in these types of schizophrenia than in normal people, and he also found that heart size differentiated catatonic and hebephrenic patients from paranoid schizophrenics. This is of special interest in view of reports that paranoid schizophrenics differ from other types of schizophrenics in physique in that they have a greater tendency to euryomorphic physique. Capillary structure in schizophrenics has also interested research workers. Olkon (1939) found that schizophrenic patients showed striking deviations from the normal in their cutaneous capillaries. The differences found included a reduction in size in the number of capillaries per unit area, lack of uniformity, bizarre shapes and the appearances of haemorrhages. Olkon (1939) considered that the severity of the disease was correlated with the degree of derangement of capillary structure. Hauptman and Meyerson (1948) studied capillary structure in the nailfold and found characteristic differences between normal subjects, paranoid schizophrenics and non-paranoid schizophrenics. This work was extended by Wertheimer and Wertheimer (1955), who found that schizophrenic patients showed thicker capillary loops than the normal, and they regarded this as being due to stasis of the blood and engorgement of the capillaries. They found that schizophrenics were also characterized by a greater length and a greater degree of visibility of the sub-papillary plexus. This feature was considered to be due to an under-development of the mesodermal layer of the skin in which the capillaries lie. Paranoid schizophrenics were found to have capillaries more similar to the normal than catatonic, hebephrenic and simple schizophrenics. They found a negative correlation with mesomorphy and the degree of plexus visibility supporting the view that low mesomorphy and high plexus visibility are both manifestations of poor mesodermal development.

Shattock (1950) also found differences in vascular functions in catatonic schizophrenics compared with paranoid patients, and he found that improvement in systemic circulation coincided with the onset of remission.

To conclude, the available evidence on the whole lends confirmation, at least in part, to Kretschmer's theory of an affinity between schizophrenia and leptosomatic, athletic and certain dysplastic physiques. The incidence of pyknic or euryomorphic body build is, however, higher in schizophrenic patients than is suggested by Kretschmer's theory. There is evidence, which is suggestive but not conclusive, that body build in schizophrenia may be related to age of onset, clinical status, course and prognosis of illness, and that paranoid schizophrenics tend to exhibit constitutional differences compared with simple hebephrenic and catatonic schizophrenics. If further research

establishes significant relationships between physique and onset of schizophrenia, its clinical forms and prognosis, the basis of such relationships may prove to be genetic, with the various genes of small effect, which determine body build, acting as modifiers to the schizophrenic gene or genes, as described by Rees (1957).

Physical Type in Relationship to Physical and Psychosomatic Disorders

PULMONARY TUBERCULOSIS

Although the description of the *habitus phthisicus* by Hippocrates clearly implied an affinity between narrow body build and tuberculosis, the association has usually been put down to the effect of the disease on body weight and physique generally rather than possibly indicating a predisposition to tuberculosis.

Recent work utilizing the findings obtained from mass radiography has helped to elucidate this age-old problem. Berry and Nash (1955) were able to demonstrate that the thickness of the skin and subcutaneous tissues measured from mass miniature radiographs, correlated to the extent of 0.86 with independent measurements of skinfold thickness made with fat calipers in the same series of individuals. They were thus able to show that subcutaneous fat may be estimated reasonably well from mass miniature radiographs and, in so doing, introduced a useful new technique for medical research.

These authors made a special study of a group of forty-nine people who had normal radiographs when first X-rayed and who later were found to have developed pulmonary tuberculosis. The interval between the first radiograph and that showing evidence of tuberculosis, ranged from two and a half to fifty-four months. They compared this group with a control group of similar age and sex distribution and matched as far as possible for occupation. They found that persons who developed tuberculosis had 17 per cent less fat than the controls.

They subdivided the groups into four types: Group 1, having long narrow chests, and Group 4, with short wide chests, with Groups 2 and 3 being intermediate. They found that individuals who developed tuberculosis had longer and narrower chests than the control subjects who did not develop tuberculosis, thus providing strong evidence in support of the *habitus phthisicus* of Hippocrates.

BODY TYPE AND ASTHMA

A number of investigators have, from time to time, claimed that there were special affinities between certain types of physique and the tendency to develop asthma. Hanse (1935) considered that asthmatics were predominantly of leptosomatic physique, and

more recently Parnell (1954), using a modification of Sheldon's method in a group of university students, also considered that asthmatic patients were predominantly of ectomorphic physique. Horneck (1940), on the other hand, put forward the view that pyknic and muscular types were associated with asthma.

Rees (1957) studied a random sample of forty-two asthmatic men by means of the Rees-Eysenck body-build index. It was found that asthmatic subjects exhibited all ranges in physique, from the marked leptomorph to the marked eury-morph. Using the criteria of Rees and Eysenck (1945), the following distribution was found: eury-morphs 9, mesomorphs 21, leptomorphs 12. The mean value was identical to that of a normal healthy group of similar age distribution. The investigation yielded no evidence to suggest any significant relationship between asthma and body build. These conclusions are in agreement with those of Young (1953), who carried out anthropometric measurements both on a group of asthmatic children and a comparable control group, finding no significant differences in bodily measurements. The results are also in keeping with the work of Brouwer (1957), who used Sheldon's somatotyping method in groups of male and female asthmatic subjects. He found that asthmatics had a variety of somatotypes and did not differ significantly in somatotype distribution from the general population.

PEPTIC ULCER

During the present century a number of investigators have been interested in investigating the relationship between body build and the development of gastric or duodenal ulcers. Westphal (1914), Bauer (1918), Tscherning (1923), and Ruhmann (1926), reported that narrow types of body build were more common among ulcer patients. Draper and co-workers, in a series of publications since 1924, have reported relationships between body build and duodenal ulcer and gastric ulcer. They claimed that ulcer individuals had a smaller depth and breadth of the chest in relationship to height. They compared the physique of ulcer patients with those suffering from gall-bladder disease and stated that the index sagittal chest diameter

length of the chest is lower in ulcer patients than those suffering from gall-bladder disease. This work is largely vitiated by the lack of satisfactory control groups and also because the age factor was not controlled. The average age for gall-bladder patients is 8.6 years higher than for the duodenal ulcer individuals, so that the difference in ages may have wholly or partly determined the differences in body measurements and bodily proportions. Feigenbaum and Howat (1934, 1935) compared sixty-seven ulcer individuals with seventy-nine diabetics and forty-six

patients with gall-bladder disease. They studied these groups anthropometrically and found no significant differences between the diabetic and gall-bladder groups on the one hand and the peptic ulcer patients on the other. This work has been criticized by Wretmark (1953) both on grounds of methodology and with regard to the conclusions made. The work of many investigators has been partly vitiated because they did not separate duodenal ulcer from gastric ulcer patients.

A very carefully planned and well-controlled study of the relationship between personality, physique and peptic ulcer, was carried out by Wretmark (1953). This study is notable for the care with which a comparable control group was obtained, investigated and assessed by the same standards and criteria as the ulcer group. Body build was assessed by Stromgren's index and by indices described by Fürst (1933). It was found that duodenal ulcer patients had a more linear type of physique than the control group. The evidence regarding an affinity between gastric ulcer patients and similar types of physique was, however, not conclusive. The investigation also showed that there was a significant relationship between body build and the course of duodenal ulcer. The more leptomorphic the body build, the worse was the course of the illness.

Draper *et al.* (1944) found that peptic ulcer individuals showed more linearity of build, and that male duodenal ulcer patients were predominantly mesomorphic. Sheldon (1940) characterized duodenal ulcer and gastric ulcer patients as lacking in endomorphy (i.e. endopenic), but Brouwer (1956) points out that Sheldon's group of ninety-two male and twenty-five female duodenal ulcer patients had a strong tendency towards endomorphic mesomorphy which would indicate a heavy, stocky build but not endopenia. Brouwer (1956) found that his ulcer patients did not show mesomorphic body build as Draper *et al.* (1944) reported, nor endomorphic mesomorphy as Sheldon's figures suggest. He found, in conformity with Wretmark (1953), that duodenal ulcer patients were more inclined to leptosomatic body build, but did not differ significantly in ectomorphy from healthy male controls or from his total groups of male patients.

GALL-BLADDER DISEASE

Draper (1944) described a gall-bladder physical type characterized by thick, round, stocky body build. Sheldon (1940, 1949) confirmed Draper's findings, and that gall-bladder patients were usually mesomorphic-endomorphic.

Draper's gall-bladder group was found to be more thick, round and stocky than his peptic ulcer patients. However, his gall-bladder group is considerably older

than his peptic ulcer group, and as the age factor is not adequately controlled, it is possible that some or all the physical differences may be a function of the age difference rather than indicating a biological affinity between gall-bladder disease and the broad, round, stocky body build.

Brouwer (1936), using Sheldon's method of somato-typing, also observed a preponderance of endomorphy in female gall-stone patients, but not significantly greater than that of a comparable healthy female control group.

CARDIOVASCULAR DISORDERS

The description of the *habitus apoplectic* by Hippocrates suggested that the broad type of body build was associated with arterial disease and presumably high blood-pressure. Support for this is given by Robinson and Brucer (1940), who found that persons with arterial hypertension are usually of wide-heavy body build and often show a tendency to obesity.

Ciocco (1936) in a review of the literature, also states that there is evidence to indicate that the pyknic type has a tendency to hypertension and cerebral haemorrhage. During recent years attempts have been made to correlate cardiovascular functions in normal subjects with physical types and Sheldon's components of physique. Tanner (1947) investigated physiological functions in fifty healthy students and found no correlation between the components of physique on the one hand, and heart rate, cardiac output and blood-pressure on the other. Parnell (1955) found that the broadest hearts were found in pyknic types, and that in asthenic people the hearts were not only narrow but were also small in relation to their body size. He found that men of muscular build had the largest hearts and the slowest pulse rates. Recent investigations have brought forward evidence that coronary artery disease has a higher incidence in more mesomorphic men (Gertler, Garn and White, 1951; Spain *et al.*, 1955).

PHYSIQUE IN RELATIONSHIP TO EFFORT SYNDROME

Effort syndrome (synonyms: neurocirculatory asthenia, Da Costa's syndrome) is characterized by marked effort intolerance, by symptoms which unduly limit the patient's capacity for effort and by a number of signs depending on functional disturbance of the autonomic nervous system when such signs are not due to any organic disease. The cardinal symptoms are breathlessness, palpitations, fatigue, left chest pain, dizziness, and the cardinal signs are those of functional disturbances of the respiratory, vasomotor, muscular and sudomotor systems (Paul Wood, 1941).

It is convenient to divide the various possible causative factors into intrinsic (constitutional) and

extrinsic. The role of physical constitution in patients suffering from effort syndrome was investigated by Rees (1944). Anthropometric measurements were carried out on groups of two hundred soldiers successively admitted to the effort syndrome unit at Mill Hill Emergency Hospital and groups of two hundred normal soldiers of comparable age and military status. A number of statistically significant mean differences in anthropometric measurements were found indicating that the effort syndrome group was significantly more narrow in body build than the control groups. Various anthropometric indices were also calculated and compared statistically. Significant differences were found in the Strömberg index and the Rees-Eysenck index, indicating that the effort syndrome group on the average was significantly more leptomorphic in body build than the normal groups.

Tanner (1951) considered that the data also provided evidence of marked differences in androgyny between the effort syndrome control group and a group of two hundred and thirty-seven Oxford students. He used formula $3 \times \text{biacromial diameter} - \text{bi-iliac breadth}$ as a measure of androgyny and based his observations only on the mean value of the group. He remarks that the most striking features in the anthropometric data appear to be large hips, narrow shoulders and short legs (i.e. symphysis height). However, as Rees (1943) demonstrated, the leg length (as shown by symphysis height) was not significantly different between the effort syndrome patients and the normal control group, that hip width was, in fact, somewhat smaller in the effort syndrome group than in the control group, but that the difference was not statistically significant. In the second group of one hundred effort syndrome patients investigated, symphysis height was in fact greater than in the control group, but the difference was not statistically significant, and in the second hundred effort syndrome patients there was a greater hip circumference than in the normal group but the difference was again not statistically significant. The first hundred effort syndrome patients were significantly smaller than the control group in biacromial diameter; the second group was smaller in this measurement but not significantly so. Measurements showing the most significant differences in both groups of effort syndrome patients compared with the control groups were transverse and sagittal chest diameters, chest circumference and chest expansion. In the second hundred effort syndrome patients the most striking difference was found in sagittal chest diameter. Tanner's assumption that effort syndrome patients are more androgynic is not therefore substantiated by the data. Rees's (1944) findings are in keeping with the work of Seltzer (1940), who found that patients of leptomorphic physique showed a much lower mechanical

efficiency when assessed by means of oxygen uptake experiments.

Patients classified under the category effort syndrome are heterogeneous both with regard to psychiatric symptomatology and in aetiological factors, showing varying proportions of intrinsic compared with extrinsic causative factors. The significance of leptomorphic physique in the genesis of effort syndrome becomes considerably elucidated when we compare effort syndrome patients with marked leptomorphic physique with effort syndrome patients with marked euryomorphic physique. This was done by Rees (1944), who found that 85 per cent of the leptomorphic effort syndrome patients had suffered from effort intolerance and symptoms of autonomic disequilibrium from an early age compared with 7 per cent in euryomorphic group; 66 per cent of the leptomorphic group had evidence of long standing personality traits of timidity, anxiety, and evidence of general neuroticism compared with 36 per cent in euryomorphic effort syndrome patients. The leptomorphic patients had a higher incidence of unsatisfactory factors in the family history of individuals with long-standing hypochondriacal tendencies. The euryomorphic effort syndrome patients were characterized by a comparatively short duration of illness. In 85 per cent the onset was less than two years before admission compared with 9 per cent in the leptomorphic group. Among the euryomorphic patients there was a higher proportion in whom exogenous factors were important aetiologically, for example, marked environmental stress, such as severe enemy action or precipitation by a febrile illness. It was, therefore, striking that leptomorphic effort syndrome patients had exhibited a predominance of constitutional factors in the aetiology as shown by the family history, longstanding symptoms of effort intolerance, autonomic disequilibrium, hypochondriasis and neuroticism. The euryomorphic effort syndrome patients on the other hand, tended to have effort intolerance of recent origin, which was often brought on by extrinsic factors such as traumatic experiences and febrile illness.

General Observations and Conclusions

The study of physical constitution has the respectable virtue of antiquity, but it is a field of investigation which has suffered from a surfeit of unverified hypotheses and a paucity of scientifically established facts. The majority of typological classifications which have from time to time been put forward, have lacked scientific basis and the entire concept of physical types in the sense of discrete and mutually exclusive categories has had to be abandoned in favour of a continuous variation ("dimensions") in body build. In order to facilitate the objective delineation of physical types, various anthropometric indices were

devised, but most of these were not based on scientifically established criteria. Knowledge of the variations in human physique have been greatly advanced by modern methods, particularly factorial analysis and techniques introduced by Sheldon (1940), Lindegard (1954) and others. Factorial analysis and allied mathematical techniques have proved to be among the most fruitful scientific approaches to the study of variations in human body build. It should be noted that very few studies have utilized measurements specifically chosen for the purpose of factorial analysis. There is clearly a need for further research by factorial methods on well-selected and representative variables relating to all manifestations of physical constitution, including configuration of the body generally and of different regions, as well as the distribution of various tissues in the body.

Faulty methodology has in the past been responsible for failure to make more rapid progress in this field of research, e.g. failure to use random or representative samples of the disorder under investigation, failure to use satisfactory control groups, failure to control factors of age, sex, race and socio-economic status, etc. In some investigations the assessment of both psychological and physical attributes by the same observer has prevented the acceptance of the reported correlations at their face value in view of the possibility that bias or "halo" effect could be responsible for part or all of the alleged correlation. Improved objective techniques are also needed for the assessment, not only of physique, but of personality, mental and clinical status.

We have seen from the survey of available evidence that the correlations between physical and psychological attributes, although often statistically significant, are usually of a low order, and it remains to be seen whether in the future higher correlations will be found where improved research techniques and methodology are used. The very high correlations reported by Sheldon (1942) between somatotype and temperament, have not been confirmed by other workers. It is, therefore, possible that the correlations between the physical, psychological, and physiological aspects of human constitution and their relationship with disease susceptibility, although statistically significant and biologically important, may not be great enough to serve the needs of diagnosis.

If further research confirms or provides further evidence of significant relationships between physical attributes, personality and susceptibility to psychiatric, psychosomatic and physical disorders, the question will still remain regarding the precise nature of the factors or processes responsible for the associations. There appear to be two main possible explanations for correlations between certain physical and psychological attributes. Firstly the association could be

due to life experiences, reactions and conditioning processes, linking different psychological attributes to different physical attributes. An alternative and more probable explanation is that they constitute integrated biological correlations between constitutional attributes. If this proves to be the case, the basis may be genetic, with the genes responsible for various aspects of body build exerting an influence on the manifestation of development of genetically determined aspects of personality and neurosis, psychosis or other illness. There is an urgent need for further genetic investigations in this field, especially in combination with longitudinal investigations of growth and development. Such investigations should, in due course, provide a body of scientifically established, valid data, regarding the interrelationships of physical, psychological, physiological disease susceptibility as integrated components of the total personality.

APPENDIX

Indices of Body Build

Pignet Index = Stature (cm) — [chest circumference (cm) + weight (kg)].

Morphological Index is a modification of that of Wertheimer and Hesketh (1926)—

$$\frac{\text{Symphysis height} \times 10^3}{\text{Transverse chest diameter} \times \text{sagittal chest diameter} \times \text{trunk length}}$$

Strömgren Index = — 0.04 stature + 0.127 transverse chest diameter + 0.56 sagittal chest diameter.

The following indices are quoted by Tucker and Lessa (1940)—

Bornhardt, A.

$$= \frac{\text{stature} \times \text{chest circumference}}{\text{weight}}$$

Brusch's Index

$$= \frac{\text{chest circumference} \times 100}{\text{stature}}$$

Rohrer

$$= \frac{\text{weight} \times 100}{\text{stature} \times \text{shoulder breadth} \times \text{sagittal chest}}$$

Von Rohden

$$= \frac{\text{symphysis height}}{\text{chest circumference} \times \text{anterior trunk height}}$$

Lucas and Pryor

$$= \frac{\text{bi-iliac diameter} \times 1,000}{\text{stature}}$$

Pignet Ver Vaeck

$$= \frac{\text{weight} + \text{chest circumference} \times 100}{\text{stature}}$$

Martin

$$= \frac{\text{bicristal diameter}}{\text{shoulder breadth}}$$

Marburg, B.

$$= \frac{\text{leg length}}{(\text{transverse} + \text{sagittal chest diameter}) \times \text{trunk length} \times \text{shoulder breadth}}$$

CHAPTER 10

Childhood Upbringing and other Environmental Factors

N. O'CONNOR and C. FRANKS

THE extensive literature on child development has often been recognized as a body of knowledge which should be integrated into general psychological theory. Inhelder (1957) draws attention to this situation and talks of some interdisciplinary studies which have made a contribution to the definition of standards of development. The attempts which are now being made to standardize criteria of developmental stages make the difficulties more apparent. Inhelder (1957), for example, talks of the failure of physiological growth stages to show a close correspondence with psychological stages. It can be said equally well that the explanatory hypotheses offered for supposed abnormalities of development are still very much at the stage of common-sense hunches. A glance at McV. Hunt's (1944) text and the chapters on child development suggests that considerable changes have been made since that time, but a review of our knowledge in any field other than the field of delinquency does not support the view that the psychology or psychiatry of abnormality in children has made notable progress. In learning studies, motivation and knowledge of social behaviour evidence is accumulating, but where neurosis and psychosis are concerned we are scarcely able to offer even a definition. Thus despite a change of emphasis we cannot claim any revelations in this field. The studies which were popular twenty years ago concerning breast feeding and oral character still appear but have not become an accepted part of general psychological theory and thus the foundation for more advanced research.

Instead, in this period, the pattern has shifted to different aspects of the mother-child relationship such as maternal deprivation and emotional dependency. But in this new field, studies continue to show a somewhat unsatisfactory set of contradictory results. Thus, although it has been shown that relationships between types of discipline and types of behaviour in

children are sometimes significant, the findings are not easily replicable. Similarly relationships between parental attitudes and psychosis in children are as frequently experimentally falsified (Nielsen, 1954) as verified (Wohl, 1954). Even the simple statement that for their later mental health the children need the affection and care of one mother, an "obviously true" statement, has turned out to be hard to prove.

It is because the field is one in which psychologists and psychiatrists have not adequately defined their problems that no complete and detailed exposition of behavioural abnormalities will be attempted in this chapter. Instead several topics have been selected either because they cover subjects which at present dominate the literature on children's mental ill health or because they represent new contributions to an established subsection of this field. In addition, one section concerned with the epidemiology of childhood disorders has been included, partly as a first attempt to draw attention to the lack of literature on this subject. No discussion of genetics or of the genetics *v.* environment controversy is included in this chapter as the subjects are dealt with in other chapters. No detailed discussion of the large subjects of mental deficiency or delinquency is included.¹ Workers in the field may also notice the omission of any considerable discussion of dreams, phantasy and play. The decision not to include a section on this subject was made because of the relatively limited output in this field. The subjects discussed in subsequent sections are dealt with critically and the authors attempt to present a point of view concerning treatment in the last section. No attempt is made, however, to cover the field of childhood abnormality by giving an exhaustive

¹ Psychological problems connected with disturbance and maladjustment among mental defectives have been discussed by Hilliard and Kirman, *et al.* (1957), Clarke and Clarke (1958) and O'Connor and Tizard (1956).

exposition. The first section introduces material which psychologists often ignore as superficially outside their scope, and its relevance to psychological problems has often been undervalued.

In some sections in which, for example, parental attitudes are discussed, it may be questioned whether or not this topic is relevant to abnormality. The reason for discussing it is, however, that a connexion has been frequently claimed and that the stages in a child's development are often held to be "fixed" by parental attitude, and may later determine the type of breakdown even if they do not determine the breakdown itself.

What is an Abnormal Child?

Discussion of child development in the past has usually been carried out in one of two ways, either relatively systematically and empirically by such workers as Gesell (1945) and Munn (1955) or from the standpoint of an existing body of theory, as in the case of Susan Isaacs (1945, 1946), Anna Freud and Burlingham (1944) or Bowlby (1952).

In the psychological study of abnormal behaviour in children, development has tended to be derivative from psychiatry, as of childhood psychosis. In some instances psychology has apparently made a contribution of its own, as in the case of the diagnosis of mild backwardness with the aid of intelligence tests. However, this situation, i.e. one in which a relatively precise definition can be given to a group of disorders, is as rare in abnormal psychology as it is in psychiatry. For this reason, for example, in a recent symposium on juvenile schizophrenia, Kanner (1954) the leading psychiatric authority on the subject said: "There are those who do not believe in childhood schizophrenia, not having seen a case. At the best, none of us have seen very many cases in which we could make a definite diagnosis, not knowing the acceptable criteria." Subsequent discussion in the symposium tended to support this view despite the fact that two contributors felt that their secretaries could always differentiate between mental deficiency and childhood schizophrenia.

Because of diagnostic difficulties in such cases as psychosis and neurosis and because of the complication of social factors in cases of delinquency and mental deficiency, it is hard to present incidence or prevalence figures which are not misleading. Mayer-Gross, Slater and Roth (1954), refer to the difference between the proportions of the sexes seen at Juvenile Courts, Child Guidance Clinics and Psychiatric Out-patient Clinics. The ratios of males to females are respectively 5/1, less than 2/1 and 1/1 for the three years 1947-1949. The authors note that under present circumstances it is impossible to say whether the figures indicate a tendency to delinquency in boys

or a failure of psychiatrists to observe it in girls. They also draw attention to the loose generalizations so current in this field concerning both diagnosis and the outcome of treatment.

Blacker (1948) has estimated that about one to two per cent of children need psychiatric guidance each year. He warns that this figure is inadequate and not based on any consistent country-wide demand, but none the less making this assumption, he estimates that about four hundred Child Guidance Centres and about one hundred and fifty Child Psychiatric Clinics would be needed, roughly six times the provision existing in 1948. These centres are named according to the suggestion of the Feversham Committee wherein the first is conceived of as dealing with educational problems and the latter with problems of abnormal behaviour. Thus the former would deal with backwardness and mental deficiency and the latter with behaviour problems, neurosis and delinquency, although in practice both act as psychiatric clinics. The emphasis here is on early treatment with the aim of avoiding mental illness in later life. The assumed connexion, however, so strongly supported by common sense is not so easily verified by experiment either in relation to psychopathy or neurosis. One aspect of this problem is presented in another section of this chapter where the concept of maternal deprivation is discussed.

Turning from the uncertain situation of psychosis in children, which is rare, and childhood neurosis, which is as yet ill-defined, to the question of delinquency and backwardness, we are on much firmer ground even if the incidence of both depends to some extent on social provision and awareness. Thus it is likely that, although diagnostic errors may account for a percentage of misclassification, ineducability or extreme backwardness equivalent to I.Q. 50 or below, will be noticed and reported before the seventh year of life in most cases. Even here, however, the availability of private education might prevent the ascertainment of a percentage of imbeciles and idiots. In the table opposite (Table X.1) figures of ascertained ineducability in some counties and county boroughs in England and Wales are given for the year 1951. The same table gives figures for the incidence of educational subnormality and ineducability in the London County Council area in 1952 and 1953.

Penrose (1949) originally noted that backwardness showed an age distribution with a peak between 10 and 14 years of age. The table in which he presents this data indicates the extent to which backwardness is a problem of the social or educational demands made on the individual.

Admission to mental deficiency institutions follows another age pattern with a peak during the 16-19 year period according to the Registrar General's figures

TABLE X.1
THE INCIDENCE OF BACKWARDNESS
A. Incidence of Severe Backwardness
and Educational Subnormality in London

	1952	1953
Number of children on school rolls.	425,362	436,921
Number recommended as E.S.N.	676	757
Number declared ineducable	73	93

B. Incidence of Ascertainment by Counties and
County Boroughs in England and Wales for 1951—
Selected Boroughs to Show Range of Ascertainment

County or County Borough	M.D. ascertainment per 1,000 population, December, 1951
Sunderland	5.79
Grimsby	5.60
Rutland	4.53
West Ham	4.37
Birmingham	4.32
Anglesey	1.22
Blackpool	1.10
Merioneth	0.90
Carmarthen	0.55
Cardigan	0.42

(1953). In a later publication (1955) he confirms this picture for the feeble-minded and presents further figures showing that cases of idiocy are hospitalized before the age of ten in about two cases out of three, whereas imbeciles are either hospitalized at this age or again during their later life from 35 onwards.

All such English studies as well as a recent study by Gruenberg (1957) in Onondaga County in New York State bring out the socio-economic distribution of feeble-mindedness with a greater prevalence in economically depressed and overcrowded regions. More severe forms of mental defect do not necessarily show this socio-economic weighting.

Overall it can be said that mental deficiency is subject to wide variation in disposal according to age, but that it is less subject to diagnostic disagreement and inconsistency over time than either childhood neurosis (maladjustment) or psychosis. As has been noted above, recent discussions show almost complete confusion on the subject of childhood schizophrenia and childhood neurosis is particularly intractable so far as definition and diagnosis are concerned.

Nevertheless, although diagnosis is often extremely difficult, children with behaviour problems and backward children come forward for treatment and their numbers are known. In 1946, for example, an estimate of E.S.N. children was given as 10 per cent

of registered pupils in schools, and maladjusted children were thought to be 1 per cent of registered pupils. This compared with about 1.3 per cent suffering from all other physical handicaps listed, such as partially sighted, blind and deaf children, delicate and physically handicapped children, and those with speech defects.

Psychological Services for Schools

In 1956 UNESCO (1956) surveyed the need for psychological services and the services existing in several European countries. This review makes the following observations concerning the United Kingdom. After describing the provision of 10,000 special school places in Scotland where there are 830,000 children of school age (1.2 per cent) and 54,000 in England with above 6,000,000 (0.009 per cent) children it adds—

Official estimates of the proportion of children needing some form of special educational treatment—not necessarily in special schools or classes—vary between about 10 per cent to as much as 15–16 per cent of the school population. From these estimates the numbers of the delinquent are omitted. It will be seen that, even allowing for the fact that, for example, many of the largest group of all, the educationally subnormal, will be accommodated in ordinary schools with a specially adapted curriculum, there is still a considerable gap between what is considered desirable and what has so far been possible. In England it is estimated that some 20,500 children are awaiting places in special schools.

The significance of the comment is further emphasized by the following figures quoted from the Ministry of Education's Annual Report for 1954 (1954)—

	<i>Number attending Special School</i>	<i>Number awaiting admission to Special School</i>
E.S.N.	21,294	12,794
Maladjusted	3,294	804

Such figures would yield an estimate of less than 1 per cent backwardness, and less than 0.1 per cent maladjustment. Even at this very low figure and, despite the existence for the maladjusted of between two hundred and three hundred child guidance clinics and centres in England, the service falls very much below the need.

The most authoritative figure for maladjustment, however, is based on three surveys carried out by the Ministry of Education (1955). In these surveys made in Somerset in 1952, Birmingham in 1953, and Berkshire in the same year, samples of 883, 2,264, and 992 were selected from school populations of 57,000, 170,000 and 39,000 respectively, with attention to

type of area and type of school but otherwise by random allocation.

Questionnaires to teachers were followed by interviews with children regarded as maladjusted. Parents were also seen and children allotted to one of five categories—

- A—very maladjusted, excluding psychosis and mental deficiency;
- B—probably maladjusted;
- C—not maladjusted, but attention needed to schooling;
- D—not maladjusted, but home conditions adverse;
- E—not maladjusted.

The surveys yielded somewhat different percentages by diagnosis in the different areas. A summary of some of the findings is given in Table X.2.

TABLE X.2
PERCENTAGE DISTRIBUTION OF SCHOOL-CHILDREN BY DEGREE OF MALADJUSTMENT

	A	B	C	D	E
Somerset .	2.7	9.1	5.3	5.6	77.3
Berkshire .	0.8	4.6	1.3	1.8	91.4
Birmingham	0.8	15.0	6.7	1.9	75.5
Birmingham (converted score) .	0.5	11.6	0.8	0.6	86.5

It can be seen that there is little overall agreement. Birmingham's figures are based on school reports and different results appear if school and parents' reports are combined. As there is only agreement between school and home on 63.8 per cent of cases, a conversion of the agreed figures has been made to equal 100 per cent. These appear on row 4 of the table and are approximations. By correction in this way figures are made to fall between those of Somerset and Berkshire so far as Category E is concerned, the major group.

Altogether the figures disagree sufficiently to show that the factors affecting referral, apart from diagnosis are still too little understood. This fact is further emphasized when we compare one other study of children referred to (1955) as having been carried out by the Tavistock Clinic with the results quoted above. In this study a maximum estimate of 42 per cent and a minimum of 35 per cent neurosis was estimated. This percentage whilst more in line with studies made with adults, such as those of Russell Fraser (1947), who found 28 per cent of neurosis in men and 36 per cent in women, is a much higher estimate than the sum of any entries in columns A and B would indicate. It is likely that some of the maladjustment reported is situational

and included some of those from column C of Table X.2.

The only conclusion one can fairly come to is that neurosis or maladjustment in children is very hard to ascertain. Attempts to assess it objectively have not met with conspicuous success. Thorpe and James (1957) report results of such an investigation which did not yield consistent objective measures presumably because of the variability of such measures with test conditions. Within the wide limits set by such deficiencies it might be guessed that a good deal of neurosis or maladjustment, apart from delinquency, exists in children possibly amounting to 15 or 20 per cent. This would lead us to expect about a million cases in a population of six million children. Even if this figure were wildly wrong and only 5 per cent were maladjusted, i.e. half the number of those known to be educationally subnormal, we would still have to consider treatment for about 300,000 children. In this area as in others it is likely that the demand will increase as more provision is made available.

The delinquent child is a further category over and above maladjusted, backward and psychotic children. In this case the nature of delinquency is such that figures are easily available. We can say, for example, that in England in 1954 there were 1,736 cases of detected crime among girls and boys aged between 14 and 17 years per 100,000 in this age group.

However, it is as well to remember that such figures, like accident figures, are partly a function of interpretation of the law and the severity with which it is enforced. It has been said that the appointment of a new chief of police in a town in the United States doubled the crime rate. For this reason it would be unwise to infer from the figures given that the delinquency rate is just over 1 per cent. It is further possible, for example, that delinquency figures overlap with maladjustment figures, just as Gittens (1952), among others, suggests that they overlap with figures for backwardness.

As little more can be attempted than a rough judgement, it would seem as if an adequate mental health service for children should be prepared to cope with 10 per cent of educational subnormality, 1 to 2 per cent of delinquency and an undetermined amount of maladjustment probably about 1 per cent of severe maladjustment and between 5 per cent and 20 per cent of milder disturbance. This means that, under present circumstances, one in three children need attention or care if they are not to suffer from their own handicaps or to fall foul of the law.

Although this section begins with a question, it may be thought by some that despite the presentation of many facts, an answer to this question has not been provided. The answer to the question is, however, implicit in the epidemiological information presented.

It, for example, opinions differ greatly from area to area about the percentage of neurotics in the population, this may be for one or more of the following reasons. Either conditions of case finding vary, or diagnostic criteria are different, or the incidence figures vary. Few sophisticated workers would offer the latter explanation before considering the two former, and in this case we have some indications that the diagnosis of even such a serious disorder as schizophrenia, presents difficulties in childhood.

If this is the case, it is likely that the diagnosis of disorders of lesser seriousness will present greater difficulties. If it is true of adults, as some maintain, that neurotic conditions remit in two-thirds of cases within two years of onset, this fact is likely to apply *a fortiori* to children where environmental factors apparently play some part in test diagnosis (Thorpe and James, 1957).

It seems likely, therefore, that clear-cut clinical entities are not apparent, and that the reason for the variability of estimates of incidence is not due to variability of incidence alone, but in a large degree to uncertainty of diagnostic criteria. It would be wrong, however, to give the impression that recognizable cases of childhood schizophrenia do not occur. They do in fact occur, although rarely. When found they are best recognized by applying criteria such as those of Bleuler (1911), for example, which would be appropriate for the diagnosis of the condition in adults. A general picture would include withdrawal, inactivity, seclusiveness and diminution of interests. Such clear-cut cases are, however, so rare that the observations made concerning the difficulties of ascertainment are relevant also to the question of definition. These are the views of Mayer-Gross, Slater and Roth (1954), although Bender (1947), stressing the importance of postural reflexes, claims to have described a clear-cut syndrome.

Natal and Pre-natal Factors Affecting Child Development

In recent years there has been a tendency for some students of child development to turn their attention to prenatal factors as distinct from those of the early environment. On the whole the literature on maternal attitudes and parental discipline, as indicated in the preceding section, although extensive, has failed to establish any hypotheses at an adequate level of proof, although in terms of learning theory, some gains have been made. (It is interesting, even so, that paediatricians have begun to examine the connexion between damage due to stresses during pregnancy and at birth and subsequent aspects of behaviour.) Psychologists themselves might do worse than turn their attention to this literature and try to devise the experiments which certainly remain to be done. The authors

know of very few psychologists in the British Isles (Stott, 1957; Rogers *et al.*, 1955), who have completed an investigation on this general question, although one or two others are in progress. (Rather more studies have, of course, been made of one aspect of birth trauma, namely the consequences of brain injury in relation to mental defect.) Discussion of the status of the literature on birth injury in this connexion can be found elsewhere (O'Connor, 1958).

This section is therefore intended to make available the findings of the very limited research programmes so far completed. Whilst extremely interesting they must, as yet, be regarded as tentative. Although the literature relative to psychological development is modern, as Rogers, Lilienfield and Pasamanick (1955) point out, associated studies date back at least to the work of Billard in 1839. Little's (1862) well-known paper on difficult labour, asphyxia and prematurity as causes of cerebral palsy and mental deficiency perhaps first revealed the importance of factors of this kind. There is no space here to discuss the development of the paediatric literature at the turn of the century concerning infant care, birth trauma and prenatal stress. Various factors have been primarily implicated as a result of different investigations. These include asphyxia, meningeal haemorrhages at birth and prematurity. However, while it was clear that such factors frequently caused death, many infants survived and their prognosis became a matter for investigation, especially in relation to neonatal asphyxia. So far results would appear to be conflicting. Many of them, however, were concerned with the intellectual development of apnoeic and premature children, and the relatively recent work of McPhail and Hall (1941) did not support the presumed association between mental retardation at school age and an apnoeic condition at birth. Whatever the prognosis for infants surviving birth accidents or intra-uterine stress, there was general agreement among investigators that such events put future mental development at risk.

Gesell and Armatruda (1947), among others, were responsible for the development of the theory of an underlying neuropathology in children suffering from dullness and personality disorders. However, whereas extensive literature exists concerning brain injury and mental defect the association with personality disorders is by no means so widely explored. In general, these have been associated with parental attitudes or other aspects of the post-natal environment.

There is only one properly controlled study of this kind available at present, that of Rogers, Lilienfield and Pasamanick (1955), mentioned above, although Stott (1957) in England has used similar methods of study to examine the antecedents of physical and mental handicap.

Rogers, Lilienfield and Pasamanick (1955), attempted

to study the birth records of behaviour-problem children in Baltimore schools. They listed behaviour problems under fifteen categories, general divisions of the descriptions of behaviour given by the teachers referring children to the Special Services Division of the Baltimore Department of Education. The percentage of children referred is usually about 4 per cent and the study reported investigated 1,800 children born on or after 1st January, 1940. Birth records were obtained for 1,151 of these children, and in about nine hundred cases they were matched with controls from the same classroom. As the labour to match the others seemed disproportionate, matching was discontinued and the groups compared as groups; four hundred and seventy-one cases and three hundred and fifty-nine controls for whom birth data were available were then compared on a number of variables. All these were single birth hospital deliveries with available birth histories and I.Q.s above 80. One hundred and thirty-three cases and fifty-seven controls, who differed from the selected groups only in having an I.Q. under 80, were studied separately.

Results from the selected groups are somewhat confused by their division into non-whites and whites, but this confusion can be lessened by reporting findings common to both the negro and white samples first and other findings later. For example, cases as distinct from controls were more frequently known to the Social Service Exchange. Cases tended to have a smaller birth weight than controls ($p > 0.05$ for whites, $p < 0.02$ for non-whites). Abnormalities of prenatal and para-natal periods were significantly greater among cases than controls ($p = 0.05$ for whites and $p < 0.01$ for non-whites).

When cases and controls with a history of abnormality of the prenatal and para-natal periods are compared, it is found that their families were registered with the Social Services Exchange significantly more often than families of cases without abnormalities.

In their general summary the authors give what may be presumed to be their most important conclusions. The appropriate inferences can be best summarized by quotation—

Cases had a significantly larger proportion of premature births than did controls and abnormalities of the prenatal and para-natal periods occurred with significantly greater frequency among cases than among controls, regardless of race. The toxemias of pregnancy (pre-eclampsia, eclampsia, hypertensive disease) and bleeding (*placenta praevia*, premature separation of the placenta, bleeding before the third trimester) constituted those maternal complications largely responsible for differences found between white cases and controls in this area. Hyperactive, confused-disorganized cases had a larger proportion of abnormalities of the prenatal and para-natal periods than cases evidencing all types of behavior disorders. Cases and controls having I.Q.s

under 80 followed the same pattern as that found among those with I.Q.s over 80, but with an increased proportion of maternal and fetal complications among cases and controls respectively.

When premature children were withdrawn from the white groups, full term white cases and controls did not differ in frequency of prenatal and para-natal abnormalities. Full term non-white children had a significantly higher proportion of abnormalities than did full term non-white controls. . . Abnormal conditions of the child at birth (asphyxia, cyanosis, convulsions, etc.) when unaccompanied by preceding maternal complications or prematurity did not differ in occurrence among cases and controls.

Abnormalities of the prenatal and para-natal periods were found to be significantly associated with behavior disorders in children. The pattern of events found in association with behavior disorders has been noted previously in fetal and neonatal mortality, cerebral palsy and epilepsy. These latter entities have been postulated to constitute a "continuum of reproductive casualty." The findings in the present study suggest that some of the behavior disorders should be added to this continuum.

The authors are critical of their findings and draw attention to the limitation of the study, especially, for example, to the fact that neurological damage which did not lead to extreme backwardness, but only to behaviour disorders, would not be serious in itself, and therefore might be difficult to detect. Another and basic shortcoming is the retrospective character of the study, and a third the obviously subjective nature of the judgements concerning types of behaviour problem.

This study, however, has put forward some suggestive findings in a field as yet little explored. Further studies are needed, but have not been forthcoming so far. In Britain the study by Stott (1957) has attempted to show a connexion between reported pregnancy troubles and backwardness, malformation and early illness. The reported results were positive, but here again criteria of reported early illness may not be sufficiently precise.

It is regrettable that so little has yet been achieved in this field where one might expect child psychologists and paediatricians to have made extensive investigations. One current study which is based on a very large sample is that of the National Survey of Child Health and Development, directed by Douglas (1958). Its findings are based on a national sample and deserve to be quoted fully, but space will allow only a very brief catalogue of findings and the barest description of method. In this section we can confine our summary of findings to those concerning prenatal and birth conditions.

The sample was selected from 13,687 children born in the first week of March, 1946, and those used in the study were originally half this number. The sample was national in the sense that it covered the whole

country. For this reason losses have been small, and losses from one area could be picked up in another so that in 1950, 5,386 children were enrolled, and in 1954, 4,452 were still taken into account. Unavoidable losses amounted to 8.9 per cent in 1950 and a further avoidable loss of 5 per cent was also recorded. According to Douglas the losses have not introduced any bias. Had the sample been local 45 per cent of the families would have been lost. Results are available by social class and at different ages.

Higher mortality in the first year of life due to pneumonia and gastro-enteritis was characteristic of lower socio-economic groups. Height followed a similar pattern with large families affecting height more adversely in the lower social groups, but not in the upper. In matters of general health, maternal care was found to be irrelevant. Other matters show a similar social gradient.

The main point of interest for this section is the comparison of the health of six hundred and seventy-six premature children with a control group born at term. The general finding was that the premature children spent more time in hospital during their first two years of life and were more susceptible to respiratory infections. Three of the premature children were mongols, two spastic and three had congenital cataract. Gross physical defects were not present in an unusual number of cases apart from these findings. Even these figures do not guarantee an unusual incidence rate for mongols for example. As one mongol would be expected in five hundred cases at the age of 10 and deaths would reduce the above quoted figures which are for the first six years of life only, it is uncertain whether or not they indicate an unusual incidence. However, the study suggests the need for further exploration.

What is very striking is that in such a field of study where results are likely to prove positive so few investigations have been made.

Parental Attitudes and the Development of Personality

One of the major controversies in this field centres around parental discipline. The question is asked: should the parents be strict or permissive? As with much of child development, expert opinions are offered and theories tenaciously held with little experimental foundation to support them.

One of the first empirical studies of this problem was made by G. Watson (1934), who examined the self-rating data obtained from two hundred and thirty graduate students. (He found that those students who came from the strictest homes tended to be more hostile to parents, not submissive and dependent, to have more social and emotional problems and to be more worried and anxious and to have more guilt feelings.) As Watson himself pointed out in a recent

publication (Watson, 1957), this study suffered from several serious defects: first, the "strict" category included homes where there was severe punishment and possibly rejection; second, the "lax" category included possible indifference and neglect as well as true concern for freedom; third, all data originated in self reports. Carpenter and Eisenberg (1938), however, came to essentially similar conclusions using a sample of five hundred college females. Myers (1935) found that adjustment in high-school children, both as measured by pupil questionnaires and by teachers' ratings, was totally unrelated to strictness of home discipline. On the other hand, Hatturck (1936) found that over indulged children from child-centred homes tended to be more babyish in that they tended to cry more readily, avoid risks and ask unnecessary help as judged by the independence expected at their age. Ayer and Bernreuter (1937) also found significant relationships between home discipline and general personality characteristics, the children from strict homes tending to "avoid reality." Symonds (1939), in a matched study which compared children from authoritarian homes with children from more permissive homes, found that the children of strict parents tended to be courteous, orderly and obedient, but at the same time they were timid and withdrawn, whereas the children of the permissive parents tended to be aggressive and less obedient but at the same time more self-confident and independent. The findings of Baldwin (1948) and Anderson (1940) confirm the latter finding. Radke (1946) studied forty-three nursery-school children by means of observation, picture interpretation tests and questionnaires to the parents. She found that children from autocratic homes showed less aggression and rivalry but were more passive and poorer in their social contact with other children, whereas children from less rigid homes were more active, showed more rivalry and were more popular with their associates. The researches of Shoben (1949) also confirm the general findings; he compared parents of children referred to clinics or brought before some juvenile authority with parents of non-problem children and found that the "problem children" parents tended to approve of strict discipline programmes and obedience much more than the non-problem parents.) The study is of particular importance because it casts serious doubt on the popularly held belief that juvenile delinquency is in part caused by lack of parental discipline and punishment. More recently Watson (1957) compared children from strict homes with children from more permissive homes, using a number of measures of personality; he failed to find any clear personality trait which was associated with any particular home background, but the general tendency was for the children from permissive homes to have the more desirable personality characteristics.

Thus, the evidence although by no means conclusive, suggests that strict parents and training produce an obedient and conforming but passive and possibly inadequate child, whereas a more permissive environment results in greater aggression but more independence and possibly better social adjustment. No one as yet has shown to what extent the children of the more permissive parents are better adjusted because of the environmental training influences of the permissive atmosphere and to what extent hereditary factors are relevant; it may be that stable parents have stable children and that stable parents tend to produce permissive patterns of child-rearing behaviour.

(It may be, too, that in a permissive environment the child gets rewarded for successfully coping with a new situation; the reward being both the allowance to carry on and to attempt a new task and the encouragement and approval at his success. The experiments of Harlow (1949) strongly suggest that successful learning facilitates further learning in animals, and it may well be that this applies to children also, i.e. learning itself becomes the reinforcement or reward.

It must be emphasized that many methodological shortcomings, even in the last work reported here, make any reliance on the findings extremely hazardous. This fact combined with the usual failure to control genetic factors because of the very great difficulty of doing so makes even these limited findings suspect; but, some experts consider that they are the best based of our recent findings concerning deviant behaviour in children.

Maternal Deprivation

If the study of child psychology and its abnormalities has begun to absorb a large percentage of the time of psychologists studying children, the study of the parent-child relationship has accounted for the largest expenditure of time and enthusiasm. Such theories are in part a movement away from the more genetic views such as those held, for example, in relation to mental deficiency by Tredgold (1908), Goddard (1923) and others in the early years of the century. In its present form the theory discussed below attributes some backwardness, some psychopathy and some emotional disturbances to "maternal deprivation." Bowlby (1952) in England and Spitz (1945, 1946) and Goldfarb (1943, 1945-6) in America have been the chief exponents of this theory and Bowlby's (1952) summary of the theory can be quoted. According to this theory "a warm, intimate and continuous relationship with his mother (or permanent mother-substitute) in which both find satisfaction and enjoyment" is essential for the mental health of the child. Such a relationship can be considered absent when the mother is unable to give the small child the loving care he

needs, but the main controversy has been based on physical separation occurring over long periods during the first two years of the child's life and perhaps during the first five years.

The straightforward statement of a separation hypothesis is not as easy as it might seem at first. Most people agree about the truth of the common-sense assumption that feral children will be backward and abnormal or that neglected and cruelly treated children will be handicapped in various ways; but even this assumption, so commonly made, is not always true as Lewis (1954) has shown. When one goes further and seeks to establish one form of theory to account for the supposed facts, difficulties become much greater.

Bowlby relies very much on the work of Goldfarb in drawing his conclusions, but this work has been criticized (O'Connor, 1956) because of the subjective nature of many of the ratings on which Goldfarb relies. The chief reason for criticizing Bowlby's reliance on Goldfarb is because Goldfarb (1945-6) has a different set of opinions from Bowlby on the effects of maternal deprivation. Goldfarb, for example, believes that children in foster-homes present emotional problems as do children in institutions, but that they are different problems. Talking of home life and institution life, he says (1945-6): "It is probable that no matter how well both kinds of care are organized, there will be some groups of children most effectively reared in one kind of atmosphere as against another." It is also clear that Goldfarb regards rejected children living at home as in a different category from maternally deprived children, whereas Bowlby at the time his monograph was published, did not.

Another main source of criticism of Bowlby's conclusions concerns the permanency of the effects of deprivation. This doctrine has been criticized by Orlansky (1949), Murphy (1944), Beach and Jaynes (1954), and Stevenson (1957). The criticisms offered by these authors can be divided into three main groups. The first is criticism of the assumption that early experience has a permanent effect, more than, for example, later experience in childhood as distinct from infancy. The second is criticism of the fact that genetics are seldom adequately controlled and may explain effects which are sometimes assumed to be due to childhood experiences. A third criticism is that children may appear to show the consequences of deprivation as permanent effects because in later life their experience does not widen to include those aspects of experience which children do not usually meet. Effects may therefore be due to causes other than maternal deprivation.

Such views are supported by a great deal of critical evidence, some of which has been summarized elsewhere (O'Connor, 1956). Evidence is drawn from

both sociological and clinical studies. For example, recovery of I.Q. following maternal deprivation has been shown by Wellman, Skeels and Skodak (1940), and recovery of self-confidence under similar circumstances by Page (1936), Clarke and Clarke (1954) have shown a rise of about 9 points of I.Q. over two years in patients who were admitted from cruel and neglectful homes and whose I.Q.s were recorded at a feeble-minded level on admission. Other studies, such as those of Lewis (1954) and Beres and Obers (1950) have shown that deprivation has by no means a consistent result in all cases. In Beres and Obers's study, deprived children followed up into late adolescence had made some sort of adjustment in all but one or two cases and half had made very satisfactory adjustments. Lewis's study examined the effect of lack of parental affection, parental neglect and a harsh depressive upbringing in children. More than one-fifth of all children admitted to a reception centre because of unsatisfactory homes were normal, although 45 per cent were definitely disturbed and nearly one-third mildly so. It was found that neglect and a dirty home do not lead to obvious psychological damage in children. Some of the figures presented show that a dirty home and a neglectful mother may be a positive advantage psychologically. The same is true of backwardness in the mother.

Several features of note were found to be associated with disturbances in the children. These were a neurotic or psychopathic mother, an affectionless mother or father, a prolonged stay in public care, and illegitimacy.

Lewis, in other words, found many factors significantly associated with disturbance in the child and not simply maternal deprivation. Of the latter she says: "Unless separation of child from mother had occurred before the age of two years and had been lasting, it bore no statistically significant relation to the normality or otherwise of the child's mental state at the time of admission." No clear connexion was evident between separation from the mother and a particular pattern of disturbed behaviour. Neither delinquency nor incapacity for affectionate relationships was significantly more frequent in the separated children.

Howells (1956) used the even more powerful technique of examining the histories of neurotics and controls for the incidence of maternal deprivation. He concludes in favour of the null hypothesis. This finding is similar to that of Ferguson and Cunnison (1951) in their review of the history of delinquent boys in Glasgow.

Several other interesting points have been made concerning the deprivation hypothesis. For example, the inconsistency of the outcome of child-rearing practices varying from extreme rigid rejection to extreme indulgence has been extensively recorded in

the sociological literature. Orlansky (1949) reviews this material. Caplan (1954) has shown that, despite conditions of relative deprivation, Kikkuta children, although showing childhood problems such as thumb-sucking, appear to be well adjusted at adolescence. Douglas (1958) has suggested that his survey of children would lead to the conclusion that children become disturbed not because mothers leave them, but because the children are separated from familiar surroundings. It may be of course that surroundings should be understood to mean "places and people."

A number of authors have remarked on the lack of connexion between maternal attitude and later mental illness. The extensive studies of mother-child relations and their effects have provided many conflicting findings but no definite conclusions. It can only be inferred that such material leaves the issue undecided.

One point not made by previous workers arises from the male/female discrepancy in delinquency and neurosis figures. In the one case, as has been frequently shown, men exceed women by a ratio of 7:1 or 10:1 between the ages of 14 and 17 years (Ford, 1957). In the case of neurosis, women tend to exceed men in some forms by about 2:1, e.g., hysterical and neurotic depressive reaction, and equal them in others, e.g., anxiety reaction. In cases where the figures are different, the deprivation hypothesis requires that more deprivation should have occurred in the sex group with the highest mental disturbance. *Prima facie* it is unlikely that women should have shown a tendency to deprive or reject one sex rather than the other. However this may be, it is impossible to explain preponderances in opposite directions on such a theory. Deprivation can therefore only be regarded as causing a very small proportion of disturbance, otherwise it would be involved in a self-contradiction. While it would be incorrect to suggest that more has been claimed for the deprivation hypothesis the sex differences do require explanation.

One other main source of evidence which has recently been called in question is that of Spitz (1945, 1946). Spitz studied the effect of the deprivation of an emotional relationship between mother and child on the maturation and development of the child. This he attempted to do by comparing groups of children from two institutions, one in which the mothers were able to care for their children and the other in which they were not. The children were cared for in the latter case by nurses who each had charge of eight children and for this reason, although motherly, were unable to give the children very much attention. This study has been evaluated by Pinneau (1955). The question is further referred to in their replies to discussion (1955). Pinneau's objections to Spitz's studies amount to criticism of the latter's failure to take account of standardization, peculiarities of test

measures and faults or subjectivity in judgement and interpretation. Such interpretations overlooked inconsistencies of statement, which leads Pinneau to assert that reported clinical symptoms supposed to be due to maternal deprivation could not have been occasioned by deprivation because it can be shown by internal evidence that the relevant time periods did not make this possible. Pinneau's main contentions are summarized (1955) as follows—

Some of the major vulnerabilities in Spitz's report of his studies may be summarized as follows: He fails to indicate the dates and places of the studies and neglects to indicate the composition and training of the research staff. He is inconsistent in his report of the number of children present in his studies, and his descriptions of their parents are contradictory. The groups which are compared as to mental and emotional development apparently differ in racial extraction, socio-economic background, and in heredity. He is inconsistent in his descriptions of their physical surroundings, of their care, and of their physical health. While most of his conclusions could only be considered plausible if based on longitudinal data, most of them are based on cross-sectional data, or at best on a mixture of the two. His reports regarding the average amount of time spent in observing the children are inconsistent, and other considerations indicate that there was a great deal of variability in the amount of time different infants were observed. He uses tests with means which apparently decrease with age. He assumes that test results at one age in infancy are highly related to test results several months later and that the same numerical quotient at different ages has the same relative significance, assumptions which are unwarranted in terms of our present state of knowledge.

The preceding conclusions make it clear that the results of Spitz's studies cannot be accepted as scientific evidence supporting the hypothesis that institutional infants develop psychological disorders as a result of being separated from their mothers.

Whilst much of Pinneau's criticisms are textual, he has raised a sufficient number of objections, especially concerning criteria of development, to call the material in question. This data, therefore, like that of Goldfarb (1943, 1945-6) and Bowlby (1952) needs further development before its conclusions can be unconditionally accepted.

Perhaps the last word on this general question should be left to Bowlby *et al.* (1956), who in recent works has considerably modified his earlier claims—

In the past, certain workers, notably Bowlby, Bender, Goldfarb and Spitz, have tended to underline both the similarities in the severely deprived children they have studied and the seriousness of the psychological damage for which they believe deprivation due to separation to be responsible. More recently others, notably Beres and Obers, and Lewis, whilst confirming that experience of separations are often pathogenic,

have emphasized the very varied clinical pictures presented by individuals who have had these experiences and the fact that a few appear to come through almost unscathed. In some of these cases, it is here argued damage of a hidden kind is probably present, although there may well be others where this is not so. Though this is a vital issue, it is one which cannot be settled without research of a far more refined character than has yet been done. Meanwhile it is clear that some of the former group of workers, including the present senior author, in their desire to call attention to dangers which can often be avoided, have on occasion overstated their case. In particular, statements implying that children who are brought up in institutions or who suffer other forms of serious privation and deprivation in early life *commonly* develop psychopathic or affectionless characters (e.g. Bowlby, 1944) are seen to be mistaken. The present investigation confirms the findings of Beres and Obers, and Lewis. Outcome is immensely varied, and of those who are damaged only a small minority develop those very serious disabilities of personality which first drew attention to the pathogenic nature of the experience.

The commendable recantation quoted here is both a tribute to the author's integrity and a demonstration of the weakness of the previous evidence from which firmer conclusions were originally expected.

Unfortunately not all workers are so ready to recognize the shortcomings of previous work and, whereas it might have been said that the weakness of developmental studies of forty to fifty years ago was their too ready reliance on genetical explanations, the besetting sin of present studies seems to be their willingness to fall back on the dynamics of mother-child relationships. In a subsequent section some aspects of early experience which may be relevant to subsequent development will be examined. These are examples of a form of deprivation of a different kind.

In concluding this section it must be noted that there is often confusion in the interpretation of reasons for the presumed effects of maternal deprivation. Some advance one kind of reason, some another. One of the more plausible explanatory hypotheses is that of too many substitute nurses. This hypothesis can be made to fit orthodox learning theory or psychoanalytic theory. It is discussed here in connexion with early manifestations of social responsiveness in the infant.

Social responsiveness begins in the first month of life when the baby begins to observe the face of an adult (Shirley, 1933).

Rheingold points out that the normative development of social behaviour has individual differences imposed on it and *in particular* environmental events modifying it. Other workers agree that social behaviour is especially susceptible to environmental events (e.g. Gesell and his associates, 1934, 1947). There is, for example, ample evidence that institutional

babies depart from normal development, such babies being (not unexpectedly) in general less responsive to people (Freud and Burlingham, 1944; Gesell and Armatruda, 1947; Spitz, 1945).

Where babies brought up in families are concerned, little is known about the factors which modify their social responsiveness. In the well-known study of Dennis (1941), social responsiveness developed normally in a pair of twins reared under conditions of minimum social stimulation. This is the only experimental evidence—and rather inadequate, since the sample size is small and the adequacy of stimulus restriction dubious. Opinions and suggestions, even when made by people of acknowledged ability such as Bayley (1932) and Jersild (1954) are of value only in so far as they suggest hypotheses which remain to be tested. For example, Jersild (1954) suggests that a baby's awareness of a stranger is a function of the experiences he has previously had with people.

One of the most recent and well-designed studies is that of Rheingold (1956), who compared a group of institutional babies, aged about 6 months, being mothered by one person, with a group who were mothered by many, using both objective tests and systematic time sampling techniques. She found that although the "one mother" group did become more socially responsive to the "mother," they failed to show more discomfort with strangers than did the other group of babies. If anything there was a tendency for the "one mother" group to be *more* friendly to strangers. This might be explicable in the terms of the generalization of a learned response, the positive response of the new contacts providing the reinforcement. Such an hypothesis requires further investigation. The above experiment indicates that social behaviour in the infant is modifiable by changes in the environment, but does not tend to confirm the Spitz and Bowlby hypothesis.

In this respect therefore, as in the critique of the factual data, the maternal deprivation hypothesis has not received confirmation in experiment to a degree which would warrant its acceptance as a guide to action. It is none the less suggestive. Work like that of Bourne (1955), for example, which attempts to link conditions of mothering to imbecility breaks new ground and deserves replication. The importance of studying parent-child relations cannot be neglected and the topic is further discussed in the concluding section.

Bowlby's exploration of the field of maternal deprivation has been severely criticized; his investigations, however, have opened up a field which is important and demands further attention. It is always possible to fault work of this kind but in this case although many of the findings are self-contradictory, the underlying hypothesis makes such an appeal by

reason of its common-sense nature that it would be ridiculous to ignore it.

Evidence Concerning Certain Psychoanalytic Hypotheses

Psychoanalytic hypotheses continue to attract much attention among students of child development. Among them the nature and effect of phases of development is popular. The first phase, the oral phase, is supposed to be dominant in the first year according to Freudian theory; the second phase, the anal phase, is supposed to be dominant from about the end of the first year until about the beginning of the fourth year, when the child is said to enter the third, or phallic, phase of his development. (During this phase the child develops an interest in his genitals, begins to masturbate more frequently, to desire physical contacts more often, especially with members of the opposite sex and manifests exhibitionistic tendencies (see Blum, 1953). During this period the child is also supposed to have sexual fantasies, usually associated with masturbation.) According to classical psychoanalytic theory, the core of this phase of personality development is the emergence of the Oedipus complex, in which the child's love for the parent of the opposite sex is confounded by hatred and jealousy of the parent of the same sex and in which the child in his fantasy life is supposed to usurp the place of his hated rival. Eventually the normal child resolves his Oedipal complex satisfactorily, the mechanisms by which this is brought about being different for boys and girls. The details of these mechanisms will be found in standard texts of psychoanalytic theory, such as those of Blum (1953) or Fenichel (1945). (In both boys and girls the Oedipal desires, if satisfactorily resolved, are supposed to be replaced by *identification* with the parent of the same sex.)

Critical reviewing of the evidence concerning such psychoanalytic hypotheses which are relevant to child development is an expanding task, but results of evaluative research may be reported as follows.

INFANTILE SEXUALITY

According to Levy (1928), over half a sample of forty-nine mothers reported that they had observed their (normal) children handling their genitals by the age of three. In another study of over three hundred problem children (Huschka, 1938), over half were reported by their mothers as having masturbated before, in many cases, the age of five.

Although orgasm or orgasmic equivalents are rare in small children, such responses are not unknown in boys and girls as young as two or three (Kinsey, Pomeroy, Martin and Gebhard, 1955; Kinsey, Pomeroy and Martin, 1952). It may well be, as

Dollard and Miller (1950) suggest in their learning theory treatment of masturbation, that the pleasure provides the reinforcement or reward for the practice to become a habit or learned response to certain stimuli. (A similar argument, of course, applies to adult sexuality of a more mature kind.)¹ Certainly, there is much evidence to support the Freudian belief in infantile sexual curiosity; many children ask sex questions before the age of five. (Hattendorf, 1932), and, according to the thorough observations of the late Susan Isaacs (1946)¹ pre-school children are commonly curious about the sexual anatomy of the opposite sex.

It is, however, difficult to test the implications of the Oedipal complex theory since it is hard to see how the very real learned dependence of a small boy on his mother can be isolated from the hypothesized sexual desire of the boy for his mother. One aspect of the theory can be examined, however, and that is the supposed universality and inevitability of the Oedipal complex. Most anthropologists and social scientists can quote ample evidence of communities where there is no evidence of *any sort* of hostility towards the parent of the opposite sex (for example, among the Hopi Indians, *see* Eggan, 1953). The most recent and exhaustive review of the anthropological literature is provided by Honigsmann (1954), who points out that when there is hostility towards the father it is more likely to be because the boy is more dependent upon the mother for his physical and emotional security.

According to orthodox psychoanalytic theory, identification takes place in the normal development of the child after the satisfactory resolution of the Oedipus conflict. Everyday experience would suggest that this is so, whatever the reason. Mowrer (1950) suggests that this is a learned habit pattern and not inevitable; according to Mowrer it is brought about by a system of selective rewards for the correct response. For example, the gratified father, pleased at seeing a miniature replica of himself in his son's behaviour pattern, rewards this pattern with praise and gifts and so the habit becomes learned. Sears and his colleagues (Sears, Pintler and Sears, 1946; Sears, P. S., 1951) have carried out extensive research on the role of the parent in developing learned behaviour in the child of the same sex. Assuming that the father provides the chief model for masculine behaviour patterns in his son, they hypothesized that his absence from home might delay the emergence of patterns such as aggression in his male children. However, since girls are hypothesized not to identify with the father but the mother, then the absence of the father should have little influence on his daughter's aggressive behaviour patterns.²

To test this hypothesis they studied the aggressive

doll play of twenty girls and twenty-two boys at each of three age levels (3, 4 and 5 years). At each level and within each group half the children came from homes with parents present, while half came from homes in which the father was away for some reason such as employment or military service. By and large, their findings confirmed the identification hypothesis, but the findings need confirmation. Other hypotheses concerning hunger and feeding have been investigated.

INFLUENCE OF THE HOME

According to reinforcement learning theorists it should be possible to predict the child's behaviour by considering the type of home he comes from. For example, if the approved (and hence reinforced) behaviour in the home is one of restriction and withdrawal, then the child should behave in a like manner outside the home.³ The studies of Baldwin and his colleagues at the Fels Institute of Human Development tend to confirm this. They developed a series of scales known as the Fels Parent Behaviour Rating Scales for the rating of children's homes on various dimensions, in many cases correlated, such as warmth, social adjustment, possessiveness, etc. They then compared the home rating on a personality attribute with the children's behaviour, as rated by nursery-school teachers and other observers, outside the home. In general, the findings supported the expectation in terms of reinforcement learning theory (Baldwin, 1948; Baldwin, 1949; Baldwin, Kalhorn and Breese, 1945; Baldwin, Kalhorn and Breese, 1949). If a learning theory rationale can be applied then one would expect the mechanism to be enhanced by some process of generalization. Bishop (1951) observed the behaviour of thirty-four children, ranging in age from 40 to 67 months, at first with their mothers, and, later, with a female adult whom the children had never seen before and who was carefully primed to react with each child in a standardized manner.⁴ Her findings strongly confirm the hypothesis that responses learned in one situation are likely to be generalized to a new situation.

It follows that, if a child can learn and carry over to new situations personality characteristics which are essentially normal, then he may equally learn and carry over neurotic characteristics. Levy (1943) made an intensive clinical study of twenty "overprotected" children. In approximately half of these cases the mothers indulged their children's every whim and the children tended to be disobedient, demanding and tyrannical at home; at school and in the playground they tended to behave in exactly the same manner. In the remaining half of the cases the "overprotection" took the form of maternal domination and overcontrol and the children tend to be withdrawn and docile; at school and in the playground they exhibited similar

patterns of behaviour in their relationships with other children and adults.

In a similar manner it has been demonstrated that children's fears are, in many cases, learned from their parents and are in many cases of the same kind (Hagman, 1932). A common fear in small children is of the dark; according to Freudian theory this is supposed to be the most basic of all fears and directly related to mother separation; in other words, it is unlearned. The evidence casts grave doubt on this hypothesis. Thus Watson and Morgan (1917) found that a six-month-old baby was not afraid of the dark and Stern (1924) in a longitudinal study found that fear of the dark did not arise until the fourth year, i.e., until the child had *learned* that the dark was a thing to be feared. Of course, if children's fears are learned responses, then they should be capable of extinction like any other learned response. The well-known studies of Watson on the development, generalization and extinction of children's fears might appear to confirm this expectation.

HUNGER

There have been many conflicting counsels about the most advisable way to handle the infant's hunger drive, e.g. on schedule, on demand, with affection or in an impersonal manner.

Can almost any pattern be conditioned or learned? How early in life can this be effected? There is evidence that even the *foetus in utero*, and certainly the neonate, can be conditioned.

D. P. Marquis (1941) was interested in the problem of the learning of a feeding schedule within the first fortnight of life. Using restlessness measured by body activity as a criterion of adaptation to the feeding schedule concerned, she compared the body activities of two groups of infants who were on two different feeding schedules. Group A (N = 16) was on a three-hour feeding schedule for the first eight days but was shifted to a four-hour schedule on the ninth day. Both groups learned their respective schedules within a few days, their body activities increasing sharply shortly before the four- or three-hour periods were up. Furthermore, when Group B was abruptly shifted on the ninth day to a four-hour schedule it still began to register increased body movements after three hours. Thus it can be concluded that even new-borns can be conditioned to a particular, externally imposed, feeding schedule.

Despite this ability to learn, it could be, as dynamically inclined child psychiatrists maintain, that certain schedules and techniques are inherently better for the child. For example, Aldrich (1947) recommends breast-feeding on demand and at the same time giving the child much demonstrative affection. Such advice is usually based on some form of psychoanalytic

theory and it is the validity of these theories which must be considered next.

THE ORAL PHASE

According to Freud the oral phase is predominant in the normal individual during approximately the first year of life. It seems reasonable that the lips and mouth become erotogenic because of its conditioned association with hunger reduction (but see Sears and Wise, 1950). According to Freud, however, sucking represents the first expressions of *sexuality* (Freud, in Brill, 1938) and is not just an unconditioned food-getting response (and later a *conditioned* pleasure response), but a basic need in itself, i.e. sucking is an innate or unconditioned *pleasure-giving* response. Davis, Sears, Miller and Brodbeck (1948) compared the oral activities (both spontaneous and in response to specific stimuli) of three groups of neonates, each group being fed by cup, bottle and breast respectively. Of these three feeding methods, clearly cup-feeding is essentially non-sucking, bottle-feeding involves much sucking, while breast-feeding requires considerable and intensive sucking. The prediction is, therefore, that, if sucking is a learned drive associated with hunger reduction, then the cup-fed group should manifest less sucking drive *in general* than the other two groups and the breast-fed group should exhibit the maximum sucking drive. Their measure of non-feeding or pleasurable sucking was the amount of time spent by each infant in sucking the experimenter's finger placed in the mouth for a fixed period each day of a ten-day period. As predicted, they found that the breast-fed group yielded consistently more and more sucking responses as the ten-day training period progressed, while the scores of the other two groups were relatively unchanged. In learning theory terms, then, sucking in general had acquired much habit strength by reinforcement in the breast-fed group.¹ The present authors must conclude with Davis *et al.* (1948) that the drive to suck in general is at least a partially learned response. The sucking reflex is of course unlearned. Freudian theory would seem to be unconfirmed in that part which asserts that the generalized sucking drive, even in non-nutritional situations, is a completely unlearned or biologically pleasurable drive (whether a sexual expression or otherwise) but supported in that aspect which suggests that the pleasure derived from stimulation of the mouth and lips is a learned response derived from an original association with hunger reduction during feeding.

The child who is breast-fed has greater opportunity

¹ It has been pointed out that the experiment is not conclusive unless it was ascertained that the breast-fed babies were satisfied. If still hungry, their increased sucking would be due very much to drive rather than habit strength.

to learn this response, hence the physiological and psychological ability of the mother to breast-feed her baby is of direct relevance. Here there is some evidence to suggest that the maternal attitude is of significance in determining the adequacy of the milk supply (Newton and Newton, 1950).

As with any learned drive, it can be reduced by many methods, both direct and indirect. Most distress is likely to be suffered, presumably, in those infants (e.g., breast-fed) in whom the drive has been developed most strongly, when the drive is thwarted or inadequately satisfied. One might, therefore, expect different reactions to weaning in such children and, also, that in breast-fed children in particular the later the age of weaning the greater the sucking-pleasure habit strength built up and consequently the greater thwarting when this drive was no longer satisfied in the customary manner. Sears and Wise (1950) compared three groups of children aged under 10 years; an early-weaned group, weaned before they were a fortnight old; a middle-weaned group, weaned before they were three months old; and a late-weaned group, weaned after four months. They estimated the degrees of weaning disturbance from an interview with the mothers, the results being as predicted, there being a positive relationship between amount of disturbance and weaning and age of weaning. It is of interest that thumb sucking, which may be regarded as a measure of oral drive, also tended to be greater in the later weaned group who had had greater opportunity to build up a strong habit strength of sucking as a drive.

According to psychoanalytic theory (e.g., Fenichel, 1945), the future personality of the infant in childhood and in adulthood is very closely dependent upon the manner in which the infantile oral pleasure drive (said by analysts to be innate and biologically determined) is satisfied or thwarted; in particular it will (according to them) depend upon the stage and technique of weaning imposed. It will, therefore, be as well to examine the experimental evidence concerning the relationship, if any, between infantile oral experiences and later personality and behaviour. In psychoanalytic terms, one might predict that children deprived of adequate oral satisfaction as babies would seek and need oral satisfaction as older children and consequently become finger suckers. On the other hand, in terms of learning theory, one might expect those children who were given considerable oral reinforcement as babies to acquire the generalized oral habits and consequently to become habitual finger suckers.

One might expect that a positive relation exists between the learned habits of finger and dummy sucking. Levy (1928), however, found none of the children in his group who were allowed to use a dummy became finger suckers. When he studied his

finger-sucking group he found that as small babies they had been nursed less often, and for briefer periods, than his non-finger-sucking group. In a much later study Levy (1934) split one litter of six puppies into three pairs. Over a period of three weeks one pair was given little opportunity for sucking and the feeds were made as short as possible by using a bottle with a large aperture in the nipple; another pair was given unrestricted opportunity to suck and the feeding bottles had tiny apertures in the nipple; the remaining pair was breast-fed by the mother. He found that the pair which had had little opportunity to suck during feeding sucked most of all in between meals, at each other's bodies and at offered fingers; the pair which were allowed unrestricted sucking at the bottle showed only a little non-restricted sucking behaviour and the breast fed pair showed none whatsoever.

Roberts (1944) found essentially similar results when he compared a thumb-sucking group with a control group of children and concluded that restricted sucking experience in infancy is a major determinant of habitual thumb sucking in later years. Thus the evidence confirms the prediction that oral deprivation in early life can lead to later oral habit patterns. Goldman-Eisler's (1951) study also confirms this finding. However, as G. Allport (1937) points out, the same results can be brought about by many different causes; there is good evidence to suggest that factors other than oral deprivation in infancy may result in thumb sucking (Simsarian, 1947).

It is also a basic assumption of many psychiatrists and diagnostically orientated psychologists that the method of early feeding (e.g., breast or bottle) produces general differences in later personality and adjustment. In many cases the clinician bases his theory on the subjective evaluation of his own case-material, and such observations have obvious shortcomings as scientific evidence. Many of the objective investigations of such theories suffer from serious methodological drawbacks. In particular, the data concerning the early infancy period are usually obtained by the introspection of some adult, and the samples studied have been both small and psychiatrically abnormal (e.g., Childers and Hamil, 1932; J. Hill, 1937). In the study by the Rogersons (1939), which successfully avoids these pitfalls, bottle-fed babies were compared with breast-fed infants in later years; the bottle-fed group was found to have a greater incidence of feeding and physical health difficulties and also to be more neurotic and to make poorer school progress. Although the sample size was unfortunately small, the data of Holway (1949) confirm these findings; she found that duration of breast-feeding was positively related to later good emotional adjustment. On the other hand, in a well-designed study, Peterson and Spano (1941) found no

relationship between duration of breast-feeding and later childhood personality and adjustment. Similarly, Sewell and Mussen (1952), in a more ambitious study, aimed at relating three aspects of feeding behaviour to later adjustment, failed to obtain any clear-cut relationships between early oral experiences and later adjustment. It is thus not possible to arrive at any definite conclusions and more research is needed; in particular, the experimental design and techniques used need improvement. Introspective and subjective data must be avoided, only valid and reliable measuring instruments must be used and the data should be subjected to statistical analysis.
